Early repolarization usually occurs in adolescents and is associated with ST-segment elevation. This is seen best in the anterior and mid-precordial leads (V2 to V4) (Fig. 15.13). Because repolarization normally begins before depolarization ends, this term is a misnomer. Elevation of the ST segment may be explained by the normal age-dependent changes of ST-segment potentials. It can mimic changes associated with pericarditis and may be confusing in the evaluation of adolescents with chest pain. With early repolarization, J-point elevation often disappears with exercise. Serial ECGs may be helpful in separating early repolarization from the typical evolution of ST- and T-wave abnormality in pericarditis. Recent attention to this pattern of "early repolarization" in adults has identified it as a significant risk factor for sudden death, but clear criteria for separating at-risk patients from the large population of normals are, so far, lacking (51).

Pericarditis and Pericardial Effusions

Pericarditis is the most common cause of ST-segment elevation in children. There are a series of changes that occur as pericarditis evolves. Initially the ST segment is elevated with a normal T wave, thought to be secondary to subepicardial myocarditis. The ST segment then returns to normal, but the

Figure 15.13. Early repolarization in a 16-year-old seen on a 12-lead ECG at full standardization. Note the 2 mm ST-segment elevation in leads V3–V6.

T wave becomes flat and then inverted. Characteristically, these findings differ from ischemic changes in that they involve all leads (46). Pericardial effusions can result in diminished QRS voltages and, rarely, electrical alternans (alternating QRS amplitude).

Myocarditis

Myocarditis usually results in flattened or inverted T waves and low-voltage QRS patterns. The QT interval may be prolonged. AV block and intraventricular conduction delay also can occur.

Ischemia

Myocardial ischemia is rare in children, but there are certain situations in which it must be considered. These include Kawasaki disease and congenital coronary artery abnormalities. Myocardial ischemia initially presents as distortion of the T wave, which becomes tall and peaked in the leads near the affected myocardial segment. The ST segment may be affected. If ischemia is reversed promptly, these changes will resolve. If ischemia persists, however, the myocardium will progress to the injury stage. The ECG may show deviation in the ST segments. The ST segments may become elevated or depressed depending on whether the injury is endocardial or epicardial. Reversal of ischemia may reverse these changes. Further injury will result in infarction, which appears on the ECG as a decrease in R-wave voltage and appearance of abnormal Q waves facing the infarcted segment (38).

Myocardial ischemia in an infant is caused by congenital coronary abnormalities, the most common being anomalous origin of the left coronary from the pulmonary artery. These infants usually present with ischemia or infarction of the anterior and septal areas (distribution of the left anterior descending coronary artery). They have deep Q waves in leads I, aVL, and V3 to V6. There also is loss of the mid-precordial R wave with a normal R wave in V1 and V6.

Kawasaki disease is an acquired cause of myocardial infarction in children. The ECG is characterized initially by low QRS voltages and nonspecific T-wave changes typical of myocarditis. These may progress to a myocardial infarction pattern.

Potassium Imbalance

Hyperkalemia produces tall peaked T waves. However, this finding is nonspecific and insensitive because normal children may have peaked T waves, and those with hyperkalemia may not have peaked T waves. As the potassium level increases, the T waves become more peaked and an intraventricular conduction delay results in a widened QRS along with PR prolongation (Fig. 15.14). The resultant ECG may resemble a sine wave or wide ventricular tachycardia. At concentrations of 9 mEq/L atrial standstill, AV block and ventricular fibrillation can occur.

Hypokalemia is associated with decreased T-wave amplitude. As potassium levels decrease, a U wave becomes apparent and the ST segment becomes depressed. Hypokalemia will enhance the arrhythmogenic effects of digoxin.

Calcium and Magnesium Imbalance

Hypercalcemia shortens the QT interval by shortening the ST segment. It also produces sinus rate slowing and sinoatrial block. Hypocalcemia lengthens the QT interval by prolonging the ST segment. A low magnesium level may enhance the effects of a low calcium level. In some infants the ECG will normalize only after both calcium and magnesium are corrected.

THE NORMAL ELECTROCARDIOGRAM

Developmental Changes

The hallmark of the ECG changes in the normal infant and child are the age-related transitions of QRS morphology, QRS duration, and the pattern of the ST segment and T wave (32,53–55). During normal development, there is a gradual decrease in heart rate and an increase in P-wave duration, PR interval, and QRS duration. Compared with those at older ages, the QRS voltages are low during the first several months of life. The mean QRS axis in the frontal plane moves in a direction from right to left. Although one might hypothesize that the observed increase in PR interval and QRS duration

Figure 15.14. A 14-year-old patient with renal failure and a potassium level of 7.7 mmol/L. The ECG shows the characteristic findings of hyperkalemia.

are related to changes in the size of the heart or the AV node, this hypothesis has not been borne out in studies in large animals.

The right ventricular dominance of the infant was one of the first age-dependent ECG changes to be recognized. The changes in depolarization of the ventricles during the first year of life occur in an orderly progression. In the newborn, the principal QRS potentials result from the right ventricle. The transition of the ECG from right ventricular dominance at birth to the pattern of left ventricular dominance lags behind hemodynamic changes. Loss of right ventricular dominance starts at about 1 month of age, and left ventricular dominance is well established by 1 year. These changes are appreciated best by the R-wave progression in the precordial leads during the first year of life. At birth and for the first several weeks of life there are tall R waves and small S waves in the right and anterior precordium (V3R, V4R, and V1), and deep S waves and small R waves in the left precordium (V6 and V7). This corresponds to a clockwise vector loop in the horizontal plane. With the establishment of left ventricular dominance, the precordial leads progress to a more adult pattern by 2 months of age, with deeper S waves in the right and anterior precordium and taller S waves in the left precordium, corresponding to a counterclockwise vector loop in the horizontal plane. At this age, however, there is still a prominent R wave in V1. By 1 year of age, the precordial R-wave progression is similar to that in the adult, with small R waves and deep S waves in the right and anterior precordium.

T waves change in a characteristic way, but the age-related patterns of repolarization are more difficult to interpret than the depolarization changes. The changes in right ventricular pressure that occur rapidly in the first days of life in normal infants have very little effect on the P wave or the QRS complex but have a great effect on the T wave. In the first minutes after birth, the T-wave vector is anterior and to the left (upright in V1 and V6). The T-wave vector may swing rightward in the next several hours, producing flattening or inversion of the T wave in the left lateral leads. Over the next 7 days, the T-wave vector moves posterior and leftward, producing an inverted T wave in V1 and an upright T wave in V6. Finally, the T wave becomes upright again in V1 after 7 or 8 years of age, but may remain inverted throughout adolescence (so-called juvenile T-wave pattern).

Preterm Infant

Compared with the ECG of term infants, the initial ECG of the premature infant is notable for its shorter QRS duration. The PR interval and QT interval also are shorter. The ECG of the premature infant is characterized by less right ventricular dominance at birth than the ECG of the full-term infant (56,57). At 1 year of age, the heart rate of the premature infant exceeds that of the term infant. Furthermore, precordial voltages are lower in the 1-year-old infant who was premature (57). The reduced precordial voltages may occur in the absence of bronchopulmonary dysplasia. Whether these differences are related to intrinsic myocardial differences of the premature versus term infant or to altered cardiac-torso geometry is unknown.

The Athlete

Athletes can have unusual ECG findings. For example, Oakley and Oakley (58) evaluated ten athletes with ECGs with voltage criteria for LVH (seven patients), nonspecific ST-segment and T-wave changes (three patients), and Q-wave changes suggestive of anterior myocardial infarction. No cardiac abnormalities were found after extensive evaluation. Balady et al. (59) reported QRS duration ≥ 100 ms in 60% of athletes, and 13% had ST-segment and T-wave changes that mimicked acute ischemia. Atrial enlargement was rare. Bjornstad et al. (60) reported athletes with sinus bradycardia and prolonged PR and QT intervals. They suggested that different criteria for ventricular hypertrophy were warranted for athletes.

Gender and Racial Differences

There are gender and racial ECG differences (61–63). The racial differences usually are not apparent until the preteen (ages 6 to 10) years. By 11 to 14 years of age, both sex and race differences are noted. It is important to know that the widely used normal standards published by Davignon (32) were based on 2,141 white children. In general, voltages in both limb and precordial leads are increased in males when compared with females and in blacks as compared with whites. Differences are not noted between black and white

females. There are differences in left ventricular posterior wall thickness among males (62). Similar findings occur in children with hypertension. It may be that the larger voltages on the ECG represent an early sign of increased left ventricular mass (64).

GUIDELINES AND INDICATIONS

In children, the primary uses of ECG include initial evaluation of patients with suspected cardiovascular disease and serial evaluation of the patient with known cardiovascular disease. The ECG is indispensable for evaluation of the patient with known or suspected disorders of rhythm and conduction, including patients with palpitations and syncope. ECGs also are indicated for determining the response to antiarrhythmic drugs or drugs with potential cardiac effects (e.g., tricyclic antidepressants). Although there is great interest in the possibility of widespread population-based screening for unrecognized cardiac disease using the ECG, there appears to be little rationale for routine ECG screening of asymptomatic, ostensibly normal young patients who are \leq age 40 years. The principal weakness of the ECG is its high rate of false positive findings, which when applied to a population with a very low prior probability, will lead to massive numbers of inappropriately identified individuals who require further testing. This argument applies to routine well-child examination as well as to pre-participation screening for athletes (65). Similarly, controversy exists regarding the need for ECG evaluation prior to the initiation of stimulant medication. While the American Heart Association has listed this as a class 2 indication (reasonable but not mandatory) (66) the American Academy of Pediatrics does not recommend such testing (67).

Cardiac Channelopathies, Syncope, and Sudden Death

Michael J. Ackerman

In the United States, an estimated 300,000 to 400,000 individuals die suddenly each year with the vast majority secondary to coronary artery disease in the elderly (1). Fewer than 10,000 of these deaths involve people <35 years of age. Sudden cardiac death (SCD) in children, adolescents, and young adults is infrequent with an incidence between 1.3 and 8.5 per 100,000 patient-years (2). Sudden death under the age of 1 year can be attributed to infection, cardiovascular anomalies, child abuse/negligence, accidents, homicide, or metabolic/genetic disorders. However, 70% to 80% of these infantile deaths have no identifiable cause and are labeled as sudden infant death syndrome (SIDS) (3,4). SIDS remains the leading cause of postneonatal infant death and the third leading cause of infant mortality overall in the United States with an estimated incidence of 0.57 per 1,000 live births (5,6).

Beyond the first year of life, the cause and manner of death can be established from a comprehensive medicolegal investigation that includes an autopsy (7,8). For nearly half of young victims from 1 to 35 years of age, there are no apparent warning signs and sudden death often occurs as the sentinel event. The postmortem investigation is critical to determine the cause and manner of death (2). A postmortem examination may detect a noncardiac cause of the death such as asthma, epilepsy, or pulmonary embolism. However, SCD is the prevailing cause of sudden death in the young, with structural cardiovascular abnormalities often evident at autopsy, including hypertrophic cardiomyopathy (HCM) (Chapter 54), arrhythmogenic right ventricular cardiomyopathy (ARVC) (Chapters 18 and 39), congenital coronary artery anomalies (Chapter 32), and myocarditis (Chapter 56) (8,9).

In contrast, approximately one-third of sudden deaths involving previously healthy children, adolescents, and young adults have no identifiable abnormalities at autopsy, and the death is classified as autopsy-negative sudden unexplained death (SUD) (7,8,10–12). The exact prevalence of SUD, particularly in children, is unclear. Potentially lethal and heritable channelopathies such as congenital long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT), and Brugada syndrome (BrS) leave no clues at autopsy. The absence of any material evidence should prompt coroners, medical examiners, and forensic pathologists to consider that a fatal arrhythmia might have caused SUD (7,13–16). Accordingly, a cardiac channel molecular autopsy, potentially, can elucidate the pathogenic mechanism and establish probable cause and manner of SUD (17–21). Most often, the arrhythmias associated with these cardiac channelopathies spontaneously return to normal sinus rhythm resulting in an episode of “just” syncope. As such, it is paramount to distinguish the ordinary benign faint from a sudden death warning sign.

In this chapter, we summarize some recent population-based investigations of sudden death in the young to better understand its frequency and causes. Next, the pathologic bases, clinical

evaluation and diagnosis, and therapeutic management of the cardiac channelopathies are detailed. Finally, we will examine the features of fainting spells that may allow discrimination between common but benign vasovagal/neurocardiogenic syncope and much rarer but, potentially lethal, cardiac channelopathy-precipitated (arrhythmic) syncope.

THE PREVALENCE AND CAUSES OF SUDDEN DEATH IN THE YOUNG

Maron et al. (8) demonstrated that HCM was the most frequent cause of SCD involving young competitive athletes. In this setting, over one-third of SCDs were attributed to HCM, and an additional 10% had an unexplained increase in cardiac mass, representing “possible HCM” (Fig. 16.1A). Autopsy-negative SUD accounted for only 3% of cases. The preponderance of athletes were male (90%) and collapsed during or instantaneously following a daytime training session (90%). Accordingly, HCM represents the most common cause of SCD on the athletic field in the United States.

In 2001, Corrado et al. (9) noted that ARVC overshadowed HCM as the most frequent cardiomyopathy associated with SCD in young Italians (Fig. 16.1B). In this autopsy review of 273 cases of Italian SCD, atherosclerotic coronary artery disease prevailed at 20% followed by ARVC (13%) and HCM (7%). Hearts were identified as structurally normal (SUD) in 6% of cases of SUD. In 2005, Puranik et al. (12) reviewed the autopsy reports from 427 young victims of unexpected sudden death (ages 5 to 35 years) over a 10-year period in eastern Sydney, Australia (Fig. 16.1C). This population-based cohort included ≥90% of all sudden deaths that occurred in this urban population during the study period. Excluded were traumatic, accidental, selected drownings, and death from drug intoxications. SCD was determined for more than half of these SUDs. Cardiomyopathies accounted for only 16% of their SCDs and only 6% of deaths were attributed to HCM. Instead, autopsy-negative SUD (29%) was the leading cause of SCD (Fig. 16.1C) with nearly 10% of the decedents with structurally normal hearts deemed to have LQTS.

Further, a 25-year review of autopsies performed on American military recruits by Eckart et al. (22) showed a non-traumatic sudden death rate of 13 per 100,000 recruit years among a monitored 6.3 million men and women aged 18 to 35 years (Fig. 16.1D). Of the 126 sudden deaths, 108 (86%) were related to exercise. Half of the sudden deaths were attributed to an identifiable cardiac abnormality after a postmortem investigation. However, 35% of the sudden deaths were classified as autopsy-negative SUD (22). Several cases were identified as having a family history of sudden premature death suggesting a heritable predisposition for a malignant arrhythmia (22).

Athletic Field SCD

Italian SCD

Australian SCD

American Military Recruits SCD

Figure 16.1. Epidemiology of sudden death in the young. A comparison of data from four cohorts. A: $N = 134$; mean age: 17 years. Frequency of cardiomyopathy subtypes: hypertrophic cardiomyopathy (HCM) 36%, dilated cardiomyopathy (DCM) 3%, arrhythmogenic right ventricular dysplasia (ARVD) 3%, and unexplained increase in cardiac mass ("possible HCM") 10%. (Maron BJ, Shirani J, Poliac LC, et al. Sudden death in young competitive athletes. Clinical, demographic, and pathological profiles. [see comment]. *JAMA* 1996;276:199–204.) B: $N = 273$; mean age: 24 years. Frequency of cardiomyopathy subtypes: HCM 7%, DCM 4%, and ARVD 13%. A significant fraction of those included in "Other structural causes" (24/38) had histological evidence of conduction system abnormalities. (Corrado D, Basso C, Thiene G. Sudden cardiac death in young people with apparently normal heart. *Cardiovasc Res* 2001;50:399–408) C: $N = 241$; mean age: 27 years. Frequency of cardiomyopathy subtypes: HCM 6%, DCM 5%, ARVD 2%, and idiopathic left ventricular hypertrophy (LVH) 3%. (Puranik R, Chow CK, Duflo JA, et al. Sudden death in the young. *Heart Rhythm* 2005;2:1277–1282.) D: $N = 108$; mean age: 19 years. Frequency of cardiomyopathy subtypes: HCM 8%, DCM 1%, and ARVD 1%. "Structurally normal" includes the diagnosis of arrhythmia disorders, such as LQTS, as well as all sudden unexplained deaths. In some instances, minimal structural abnormalities were noted at autopsy, but these were felt to be insufficient to cause sudden death. †"Cardiomyopathy" includes those with HCM, DCM, ARVD, and those with unexplained increase in cardiac mass not meeting strict criteria for HCM (i.e., "possible HCM"). CAD, coronary artery disease. (Eckart RE, Scoville SL, Campbell CL, et al. Sudden death in young adults: a 25-year review of autopsies in military recruits. *Ann Intern Med* 2004;141:829–834, Ref. 22; From Tester DJ, Ackerman MJ. The role of molecular autopsy in unexplained sudden cardiac death. *Curr Opin Cardiol* 2006;21:166–172, with permission, Ref. 23.)

Morentin et al. (11) scrutinized all sudden nonviolent deaths in persons 1 to 35 years of age occurring in Spain from 1991 to 1998. Among the 107 cases of sudden death, 18% were considered SUD. Thirteen died following sudden collapse, and six were discovered dead in bed. In one-fifth of these SUDs, death occurred in relation to physical exertion (including swimming) or extreme emotion. Antecedent

symptoms compatible with cardiac arrhythmia were evident in >25% of the SUD cases.

These population-based studies suggest that while the majority of SCD stem from identifiable morphologic abnormalities found at autopsy, nearly one-third of sudden deaths involving previously healthy children, adolescents, and young adults are autopsy-negative SUD.

AUTOPSY-NEGATIVE SUDDEN UNEXPLAINED DEATH

Assessment of Family Members

In cases of autopsy-negative SUD, a cardiac and genetic evaluation of first- and second-degree relatives and/or a molecular autopsy may elucidate the underlying mechanism of the sudden death. Although arrhythmias can be isolated events, some may represent manifestations of inherited arrhythmia syndromes with increase risk for syncope, cardiac arrest, or SCD in relatives when there is a family history of sudden death. Thus, first-degree relatives of the decedent should have a comprehensive cardiovascular evaluation including an extensive personal and family history, physical examination, 12-lead electrocardiogram, treadmill stress test, 24-hour Holter monitoring, and an echocardiogram.

In 2003, Behr et al. (10) performed a detailed cardiovascular evaluation of 109 first-degree relatives of 32 cases of SUD and showed that 22% of these families had evidence of inherited cardiac disease with the majority having features suggestive of LQTS. Similarly, in 2005, Tan et al. (24) found that 28% of families had an identifiable cardiac channelopathy including CPVT and LQTS following a clinical assessment of first-degree relatives of young SUD victims. In a 2008 follow-up study by Behr et al., a diagnosis of inheritable heart disease was made in 53% of first-degree relatives of SUD victims following a comprehensive clinical evaluation; 70% being diagnosed with either LQTS (53%) or BrS (17%). Strikingly, 30% of the families evaluated reported a family history of additional unexplained premature sudden deaths under the age of 45 years, and nearly 20% of the decedents had a prior history of syncope.

In 2010, van der Werf et al. identified a certain or probable diagnosis in 47 (33%) of 140 families of SUD victims (aged 1 to 50 years) following a clinical cardiac assessment. Around 96% of these 47 families were diagnosed with an inherited cardiac disease (21% LQTS, 17% CPVT, 15% BrS, and 15% ARVC). The diagnostic yield among families depended upon the age of the decedent ranging from a high of 70% when the decedent was between ages of 1 and 10 years to a low of 21% when the decedent was between 41 and 49 years of age. Many of these sudden death victims had antecedent warning signs prior to their own death, including syncope in 15% and a family history of young sudden death in 29%. However, there was no prior clinical diagnosis of an inherited cardiac disease for either the decedent or any other family member.

Incomplete penetrance and variable expression are hallmarks of the various cardiac channelopathies that lead to “concealed” forms of these disorders (25). Therefore, clinical assessment of surviving family members of SUD victims may be insufficient to detect LQTS, CPVT, or BrS in unsuspected individuals. A molecular autopsy involving postmortem cardiac channel genetic testing is a tool for the forensic pathologist/medical examiner/coroner to provide the answer to unexplained deaths in the young and subsequently benefit other family members.

Molecular Autopsy Investigations of SUD

In 2004, Chugh et al. (21) identified 12 cases of SUD following a comprehensive postmortem analysis of a consecutive series of 270 adult (age ≥ 20 years) cases of SCD occurring over a 13-year period. Postmortem genetic analysis of the LQTS-susceptibility genes revealed an identical *KCNH2* mutation in 2 of these 12 (17%) cases of autopsy-negative SUD. Similarly, Di Paolo et al. (26) performed LQTS molecular autopsies on

10 cases of juvenile (ages 13 to 29 years) SUD and identified *KCNQ1* mutations in 2 individuals.

In 2007, Tester and Ackerman completed the largest molecular autopsy series of SUD to date (27,28). Comprehensive mutational analysis of all 60 translated exons in the LQTS-associated genes (*KCNQ1*, *KCNH2*, *SCN5A*, *KCNE1*, and *KCNE2*) along with targeted analysis of the CPVT1-susceptibility gene (*RYR2*) was conducted on a series of 49 medical examiner referred cases of SUD. Over one-third of these SUD cases had a presumably pathogenic cardiac channel mutation with mutations in *RYR2*, alone, accounting for nearly 15% of the cases (27,29). In this series, sudden death was the sentinel event in all but four mutation-positive SUD cases. However, many had a positive family history of cardiac events, yet no family members had been diagnosed with either LQTS or CPVT. Overall, approximately half of the 17 decedents with a cardiac channel mutation detected by postmortem genetic testing exhibited potential warning signs, either personally or in the family. The repeated observations of unheeded warning signs of syncope and/or family history of sudden death in nearly 15% to 30% of young SUD victims emphasize the importance of heeding potential warning signs.

Population-based studies involving the evaluation of relatives and molecular autopsy investigations of the decedent show that identifiable and potentially treatable cardiac channelopathies (including LQTS, CPVT, and BrS) account for approximately one-third of autopsy-negative SUD in the young. In addition, approximately 10% to 15% of SIDS may be due to these cardiac channelopathies (19,30–36).

THE CARDIAC CHANNELOPATHIES

The discipline of *Cardiac Channelopathies* unofficially commenced in 1995 with the discovery of mutations in genes encoding critical ion channels of the heart as the pathogenic basis for congenital LQTS (37,38). Besides classical autosomal dominant (Romano-Ward) LQTS and autosomal recessive (Jervell and Lange-Nielsen) LQTS, the cardiac channelopathies now include Andersen-Tawil syndrome (ATS), Timothy syndrome (TS), drug-induced *torsades de pointes* (DI-TdP), short QT syndrome (SQTS), CPVT, BrS, idiopathic ventricular fibrillation, early repolarization syndrome, progressive cardiac conduction disease or familial atrioventricular conduction block or Lev-Lenegre disease, and familial atrial fibrillation. Even primary cardiomyopathies like dilated cardiomyopathy (DCM) can be due to genetically mediated perturbations in ion channels, specifically the *SCN5A*-encoded cardiac sodium channel (37–39).

Overall, cardiac channelopathies may affect as many as 1 in 1,000 persons, may lie dormant for decades or present with SIDS, and may or may not manifest signature electrocardiographic features (Fig. 16.2). Collectively, these cardiac channelopathies represent treatable conditions when recognized. In general, the cardinal events of the cardiac channelopathies comprise *syncope*, *seizures*, and *SCD*. Unfortunately, SCD can be the sentinel event.

Autosomal Dominant Long QT Syndrome (Romano-Ward)

Congenital LQTS is the prototypic cardiac channelopathy with an estimated prevalence of 1 in 2,000 to 2,500 persons. Clinically, LQTS is characterized by abnormal cardiac repolarization resulting in QT interval prolongation (Fig. 16.2A) that predisposes patients to TdP (Fig. 16.2B). Palpitations seldom represent the sole indicator of an episode of TdP. The

Figure 16.2. Signature electrocardiographic features of various channelopathies. A: QT prolongation—an example of a patient with extreme QT prolongation ($QT_c > 650$ ms). Note, the ST segment and T-wave morphology would predict LQT3, but this patient is among the 25% who are genotype negative. Also, the computer-calculated QT_c was 362 ms underscoring the mandate to independently compute the QT_c . B: *Torsade de pointes* (“twisting of the points”)—hallmark arrhythmia of LQTS. C: Abnormal U wave in ATS—although subtle, this lead II recording is quite abnormal characterized by normal QT interval, long isoelectric segment between the end of the T wave on the start of the U wave and long-duration U wave in this female with an ATS1-associated mutation in *KCNJ2*. D: Short QT interval— QT_c of approximately 250 ms. E: Exercise-induced bidirectional VT seen in CPVT. F: Coved ST segment elevation in BrS (type I Brugada ECG pattern) in precordial leads V1 and V2 and a saddle back profile (type II Brugada ECG pattern) in V3. (From Ackerman MJ. Heritable cardiac channelopathies. In: Wyszynski DF, Correa-Villasenor A, Graham TP, eds. *Congenital Heart Defects: From Origin to Treatment*. New York, NY: Oxford University Press, 2010:131–140, with permission, Ref. 40).

most common form of LQTS is autosomal dominant LQTS, previously known as Romano-Ward syndrome (41,42).

Hundreds of mutations in 13 distinct LQTS-susceptibility genes have been identified and generally involve either loss-of-function potassium channel mutations or gain-of-function sodium channel mutations. Except for four rare subtypes that stem from perturbations in key cardiac channel interacting proteins or structural membrane-scaffolding proteins (ankyrin B-, caveolin 3-, yotiao-, and syntrophin α -LQTS) (43–46), LQTS is a pure “channelopathy” resulting from mutations in cardiac channel α - and β -subunits. The majority of LQTS is due to mutations in either the *KCNQ1*-encoded I_{Ks} potassium channel (LQT1, 30% to 35%), the *KCNH2*-encoded I_{Kr} potassium channel (LQT2, 25% to 30%), or the *SCN5A*-encoded I_{Na} sodium channel (LQT3, 5% to 10%) (47,48).

The past decade of LQTS research has provided numerous genotype–phenotype relationships (Fig. 16.3). Genotype–ECG

relationships include broad-based T waves in LQT1, low-amplitude or notched T waves in LQT2, and long ST isoelectric segment with normal T-wave morphology in LQT3 (51,52). Gene-specific arrhythmia triggers have been observed including: exertion in LQT1 (particularly swimming), auditory triggers and the postpartum period in LQT2, and events during sleep in LQT3 (49,53–56). Importantly, the response to β -blockers is strongly influenced by the underlying genotype with which patients with LQT1 realize superior protection than patients with either LQT2 or LQT3 (57).

In the presence of a clinical diagnosis of LQTS, the yield of LQTS genetic testing is about 75% (58). Generally accepted indications for LQTS genetic testing are summarized in Table 16.1. However, genetic tests for LQTS and the other cardiac channelopathies must be scrutinized and interpreted with great caution and must not be viewed as binary tests (50,59). These genetic tests are probabilistic tests. Some mutations will

Figure 16.3. Genotype–phenotype correlations in LQTS. Seventy-five percent of clinically strong LQTS is due to mutations in three genes (35% *KCNQ1*, 30% *KCNH2*, and 10% in *SCN5A*) encoding for ion channels that are critically responsible for the orchestration of the cardiac action potential. Genotype–phenotype correlations have been observed, including swimming/exertion and LQT1, auditory triggers/postpartum period and LQT2, and sleep/rest and LQT3. The bar graphs represent genotype–phenotype data from Ref. 49. Also illustrated is the relative gene-specific effectiveness in β -blocker therapy where β -blockers are extremely protective in LQT1 patients and moderately protective in LQT2 and LQT3. Direct late sodium current blockers like mexiletine, flecainide, and ranolazine may be protective in LQT3. (From Tester DJ, Ackerman MJ. Genetic testing for potentially lethal, highly treatable inherited cardiomyopathies/channelopathies in clinical practice. *Circulation* 2011;123:1021–1037, with permission, Ref. 50.)

be definite disease-causative mutations, whereas other genetic variants may not be pathogenic (50).

Individuals with LQTS may or may not display the hallmark repolarization abnormality of QT interval prolongation (Fig. 16.2A). In fact, approximately 40% to 50% of patients with genotype-positive LQTS have a normal resting QTc (25). This observation reinforces the critical role of genetic testing. In general, a heart rate-corrected QT interval (QTc) > 480 ms in *postpubertal* females or > 470 ms in *postpubertal* males should prompt a thorough investigation for LQTS. These values represent the 99th percentile in the distribution of QTc values. Previously, a QTc > 440 ms (males) or > 450 ms (females) has been considered “borderline” QT prolongation. In fact, the 2009 AHA/ACC/HRS (American College of Cardiology/American Heart Association/Heart Rhythm Society) guidelines denote that a QTc \geq 450 ms in adult males

and \geq 460 ms in adult females must be considered “prolonged QTc.” Although 50% of patients with genetically proven LQTS have a QTc < 460 ms, these cutoff values would result in an unacceptably high rate of false positives if used as part of a screening program. Using these cutoff values, an estimated 15% to 20% of the entire population would have “borderline QT prolongation” and 5% to 10% of adults would satisfy the guidelines definition of “prolonged QTc” (Fig. 16.4). In addition, these QTc values are based upon an accurate measurement of the QTc (62). It is absolutely critical to measure the QTc manually. Relying on the computer-derived QTc is unacceptable. Calculation of an average QTc from either lead II or V5 is recommended. Simply using the beat yielding the maximum QTc yields too many false positives. Furthermore, these QT distributions do not apply to 24-hour ambulatory ECG recordings.

TABLE 16.1 Generally Accepted Indications for LQTS Genetic Testing

1. Persons with unequivocal and unexplained QT prolongation (i.e., QTc \geq 500 ms).
2. Persons with clinically suspected LQTS regardless of (a) baseline QTc or (b) history of prior negative genetic testing in research laboratories or with commercially available targeted exon testing. (Rationale: Mutation detection methods over the past decade have changed significantly and false negatives have been demonstrated.)
3. All first-degree relatives of a genotype positive index case (genetic testing extended to other degrees of relatedness by “following the genetic trail” down the appropriate path of concentric first-degree relatives). For example, confirmatory genetic testing demonstrates the index case’s LQT1-associated mutation in the father. Accordingly, the father’s parents and siblings (second-degree relatives to the index case) should be offered testing. Next, if, say, the paternal aunt (to the index case) tests positive, now all of her children (cousins or third-degree relatives to the index case) should be tested and so forth.

Figure 16.4. Distribution of QTc in health and LQTS. Shown is the distribution of QTc values derived from healthy postpubertal males and females (Mason JW, Ramseth DJ, Chanter DO, et al. Electrocardiographic reference ranges derived from 79,743 ambulatory subjects. *J Electrocardiol* 2007;40:228–234, Ref. 60). The QTc distribution for LQTS is derived from analysis of the ECGs of all patients with mutation-proven LQTS who have been evaluated in Mayo Clinic's LQTS Clinic. (Adapted from Taggart NW, Haglund CM, Tester DJ, et al. Long QT syndrome. *Circulation* 2007;115:2613–2620; Johnson JN, Ackerman MJ. Long QT syndrome. In: Yan G, Kowey PR, eds. *Management of Cardiac Arrhythmias*. New York, NY: Humana Press, 2011:419–440, with permission, Ref. 61.)

Efforts to unmask concealed LQTS (genotype-positive/resting ECG negative) include exercise stress testing and epinephrine QT stress testing (63–67). With exercise stress testing, failure to shorten the QT interval appropriately suggests LQTS. However, this failure to shorten during exercise is principally an LQT1-specific response. Thus, the presence of normal QT interval shortening during exercise does *not* exclude LQTS. Similarly, during infusion of low-dose epinephrine (≤ 0.1 mcg/kg/min), the presence of paradoxical lengthening (>30 ms) of the absolute QT interval is suggestive (75% positive predictive value) of concealed LQT1 (68).

The features present in the composite clinical diagnostic scorecard known as the “Moss, Comptom, and Schwartz LQTS score” should be used to gauge the clinical probability of the presence of LQTS in an index case (Table 16.2) (69). This score includes ECG parameters (QTc, TdP, T-wave alternans, and notched T-waves) and the personal and family history. Importantly, this score does not apply to family members. In addition, the metrics utilized are more sensitive than specific. For example, an asymptomatic 17-year-old girl with no family history but a QTc of 481 ms is awarded 3 points and a qualitative label of “intermediate probability” LQTS. Although statistically more likely to have LQTS than a woman with the same story but a QTc of only 420 ms, this “intermediate probability” LQTS-labeled female still has *only* a 4% chance of actually having LQTS. One must avoid not only missing LQTS when it is there but also overdiagnosing it when it is not there. In our center, approximately 40% of the patients who have sought a second opinion following a diagnosis of LQTS were dismissed as otherwise healthy (70). Common and recurring miscues included miscalculation of the QTc and overinterpretation of the significance of a borderline QTc value in the context of nonarrhythmic syncope.

Overall, the annual mortality associated with LQTS is around 1% per year with the highest risk subset around 5% to

TABLE

16.2

Clinical Probability Scores for Index Case Evaluation for SQTS and LQTS

SQTS	Diagnostic Criteria	LQTS
ECG parameters—must be included in the diagnosis		
QTc (Bazett formula)		
	≥ 480 ms	3
	460–470 ms	2
	450–459 ms (males only)	1
0	371–459 ms (“normal” QTc for female patient)	0
0	371–450 ms (“normal” QTc for male patient)	0
1	351–370 ms	
2	331–350 ms	
3	<330 ms	
	Torsade de pointes ^a	2
	T-wave alternans	1
	≥ 3 leads with notched T-waves	1
	Bradycardia (<2 nd percentile for age)	0.5
1	Jpoint–Tpeak interval < 120 ms	
Clinical history		
2	History of sudden cardiac arrest	
2	Documented polymorphic VT or VF ^a	
1	History of syncope ^a	
	Without stress	1
	With stress	2
1	Atrial fibrillation	
	Congenital deafness	0.5
Family history		
	Family history of LQTS ^b	1
2	Family history of SQTS ^b	
1	Unexplained sudden death: first-degree family member $< \text{age } 30^b$	0.5
1	Sudden infant death syndrome (SIDS) ^b	
Genotype		
2	Genotype positive	
1	Variant of uncertain significance (VUS) in a culprit gene	

Low probability: ≤ 2 points (SQTS), ≤ 1 point (LQTS); intermediate probability: 3 points (SQTS), 2–3 points (LQTS); and high probability: ≥ 4 points (SQTS and LQTS). Electrocardiogram must be recorded in the absence of modifiers known to shorten or lengthen the QT interval. Jpoint–Tpeak must be measured in the precordial lead with the greatest amplitude T wave. A minimum of 1 point must be obtained in the ECG section in order to obtain additional points.

^aSyncope and torsade de pointes are mutually exclusive.

^bCannot count the same family member twice. VF, ventricular fibrillation; VT, ventricular tachycardia. SQTS criterion adapted from Gollob MH, Redpath CJ, Roberts JD. The short QT syndrome: proposed diagnostic criteria. *J Am Coll Cardiol* 2011;57:802–812; LQTS criterion adapted from Schwartz PJ, Moss AJ, Vincent GM, et al. Diagnostic criteria for the long QT syndrome. An update. *Circulation* 1993;88:782–784.

8% per year. Indicators of increased risk for SCD include a QTc > 500 ms (71,72), a history of TdP-mediated syncope (72,73), prepubertal males and postpubertal females (74), and events occurring during the first year of life (75). Genetic risk factors include multiple mutations, LQT2 or LQT3 genotype (71), and the presence of higher risk mutations based on molecular location and cellular function (76–81). Both symptomatic and asymptomatic patients with LQTS must avoid medications that prolong the QT interval (www.qtdrugs.org). In addition, patients should maintain adequate hydration/electrolyte replenishment in the setting of vomiting and diarrhea that could cause hypokalemia. Asymptomatic patients >40 years of age, especially those with nondiagnostic QTc values at rest, may not require active intervention but this must be individualized.

In general, all symptomatic patients and all asymptomatic patients <40 years of age should receive medical, surgical, and/or device-related therapy. β -Blockers, preferably nadolol or propranolol, should be considered standard therapy for all patients with either LQT1 or LQT2 (57,82). In contrast, the protective role of β -blockers for patients with LQT3 is controversial and confusing. Initial clinical reports failed to demonstrate clear efficacy (57). Subsequently, *in vitro* cellular studies raised the concern of a possible proarrhythmic effect of β -blockers for LQT3 (83). These observations likely catalyzed the overuse of internal cardioverter defibrillators (ICDs) in the management of patients with LQT3 (84,85). β -Blocking drugs, particularly propranolol, are reemerging as initial treatment of choice for LQT3 (unpublished data). Additionally, genotype-targeted therapy with late sodium current blockers such as mexiletine, flecainide, or ranolazine may be considered as stand-alone or concomitant therapy with propranolol (57,86,87).

Despite a class IIb guideline recommendations for an ICD in any patient diagnosed with LQTS (88), more appropriate indications for an ICD include (a) aborted cardiac arrest (regardless of genotype) as secondary prevention, (b) breakthrough cardiac event despite adequate medical therapy, (c) intolerance of primary pharmacotherapy, and (d) prior LQTS-triggered cardiac events plus QTc > 550 ms (particularly in LQT2 women) (84,85,89). In general, a single lead ICD system is preferred unless pacing is required. Conversely, there is probably little role for pacemaker-only therapy except possibly in LQT2 when a pause-dependent premature ventricular contraction triggering mechanism is suspected or documented. Usually however, if a pacemaker is contemplated for therapy, a dual-chamber PM/ICD should be utilized instead.

A unilateral left cardiac sympathetic denervation (LCSD) involving surgical ablation of the lower half of the left stellate ganglion along with the left-sided thoracic ganglia T2 through T4 is indicated either for patients receiving recurrent ventricular fibrillation (VF)-terminating ICD shocks or patients who do not tolerate adequate doses of appropriate drugs (90,91). LCSD also could be considered for patients with a pharmacotherapeutic breakthrough events. Also, LCSD may be useful as a “bridge to ICD” for those patients at high risk for an LQTS-triggered cardiac event but who are high risk for ICD-related complications such as infants and children. According to the 2005 Bethesda Conference no. 36 guidelines, competitive sports are restricted (except class IA activities of golf, cricket, bowling, billiards, and riflery) in all patients with symptomatic LQTS (except possibly LQT3) (92). However, these guidelines/expert opinion-based recommendations are not accepted uniformly within the community of both pediatric and adult heart rhythm specialists especially for the athlete with LQTS and an ICD (www.icdsportsregistry.com) (93,94). Currently, there is guidelines-based support for relaxing these competitive sports restrictions for patients with concealed LQTS defined as genotype positive but asymptomatic with QTc < 480 ms in females and <470 ms in males.

Autosomal Recessive LQTS (Jervell and Lange-Nielsen)

In contrast to Romano-Ward LQTS, autosomal recessive LQTS (Jervell and Lange-Nielsen syndrome, JLNS) is extremely rare affecting one per million persons. The cardiac phenotype generally is more severe and, in fact, primary prevention with a β -blocker plus ICD therapy or β -blocker plus LCSD therapy is indicated for JLNS. JLNS involves homozygous or compound heterozygous (“double hit”) mutations in the I_{Ks} potassium channel. Type 1 JLNS (JLN1) arises from such double mutations in *KCNQ1* (i.e., double LQT1), whereas type 2 JLNS (JLN2) stems from double mutations in *KCNE1* (double LQT5). These genes encode, respectively, the Kv7.1's α - and β -subunits of the critical phase 3 repolarizing potassium current, I_{Ks} . By definition, both parents of a child with JLNS are obligate affected individuals with either LQT1 or LQT5. That is, the cardiac phenotype in JLNS is a dominant trait although the parents generally have an asymptomatic course and minimal, if any, manifest QT prolongation. In contrast, the deafness is a recessive trait. This same I_{Ks} potassium channel is critical for potassium homeostasis of the endolymph in inner ear.

Multisystem or Complex LQTS

ATS is a multisystem disorder that includes skeletal and facial features, periodic paralysis, and abnormal cardiac repolarization. Loss-of-function mutations involving the *KCNJ2*-encoded inwardly rectifying potassium channel (Kir2.1) is implicated in the pathogenesis of approximately 50% to 60% of ATS (95). Unlike the classical forms of LQTS, however, the abnormal repolarization in ATS1 is better characterized as normal QT interval, prolonged QU intervals, with prolonged/abnormal U waves (Fig. 16.2C) (96). The incidence of sudden death is less in ATS than the major subtypes of LQTS.

TS is a rare multisystem disorder that includes abnormal cardiac repolarization, syncope and sudden death, syndactyly, and significant learning disability. Mutations in the α subunit of the L-type calcium channel ($Ca_v1.2$) encoded by *CACNA1C* (particularly a specific missense mutation G406R) have been identified (97). The mutation results in near complete loss of voltage-dependent channel *inactivation* of $Ca_v1.2$ producing QT prolongation secondary to increased calcium influx (i.e., gain-of-function phenotype). Although extremely rare, TS is associated with a very severe phenotype, and primary prevention ICD therapy probably is indicated. Like LQTS, genetic testing for both ATS and TS is available.

Short QT Syndrome

There are three genetic subtypes of SQTS, each representing the antithesis of loss-of-function, potassium channel-mediated LQTS, and ATS (98–101). The three SQTS subtypes stem from gain-of-function mutations in *KCNH2*, *KCNQ1*, and *KCNJ2*. These mutant potassium channels accelerate cardiac repolarization. Electrocardiographically, the characteristic ECG finding is a short QT interval (QTc \leq 330 ms), with tall, symmetrical, peaked T-waves (Fig. 16.2D).

Recently, diagnostic criteria for SQTS have been proposed. The SQTS score awards points not only for the QT interval but also for the personal and family history (Table 16.2) (102). These patients present with sudden death, syncope, palpitations, and, sometimes, paroxysmal atrial fibrillation. The age at which sudden death occurs varies from 3 months to 70 years. Most patients have a family history of sudden death. The degree of incomplete penetrance, variable expressivity, and overall prevalence of SQTS are poorly understood. However, SQTS is thought

to be much less common than LQTS. Examples of family members who are genotype positive for a SQTs-associated mutation but a normal resting QT interval have been reported.

Most patients have easily inducible VF during electrophysiologic studies and have short atrial and ventricular refractory periods. The therapy of choice is an ICD. However, these patients are at increased risk of inappropriate shocks from T-wave oversensing. ICD detection algorithms may decrease the risk of inappropriate shocks. Adjunctive pharmacotherapy with drugs like propafenone, quinidine, dofetilide, or sotalol may help prolong the QT interval and decrease the potential for VF.

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is characterized by exercise/stress-induced syncope and/or sudden death in the setting of a structurally normal heart with a normal QT interval (103). CPVT clinically mimics concealed type 1 LQTS but is far more malignant than concealed (normal QT interval) LQTS. In fact, 3% to 4% of patients referred for LQTS genetic testing actually have CPVT-associated mutations (104). Initially, CPVT was described in children, but more recent studies suggest that the age at presentation can vary from infancy to 40 years. In one-third of patients with CPVT, there is a family history positive for juvenile sudden death (105). The hallmark electrocardiographic feature of CPVT is exercise or isoproterenol-induced ventricular arrhythmias, particularly bidirectional VT (Fig. 16.2E). However, the vast majority of mutation-proven CPVT patients in our clinic never have exhibited CPVT's trademark arrhythmia during stress testing. Also, bidirectional VT during exercise has been reported in ATS and LQTS. Importantly, a patient with a history of exertional syncope, normal QT interval at rest, and exercise-induced ventricular ectopy is far more likely to have CPVT than LQTS. Moreover, a history of exercise-induced seizures should prompt investigation for the possibility of either LQTS or CPVT before concluding that it is epileptogenic in origin (106–108).

The pathogenic substrates for CPVT involve key components of intracellular calcium-induced calcium release from the sarcoplasmic reticulum. Type 1 CPVT (CPVT1) stems from mutations in the *RYR2*-encoded cardiac ryanodine receptor or calcium release channel and accounts for approximately 60% of CPVT (109,110). Mutations in *RYR2* confer a *gain-of-function* phenotype to the calcium release channel resulting in increased calcium leak during sympathetic stimulation, particularly in diastole. In contrast to the autosomal dominant/sporadic CPVT1, CPVT2 is autosomal recessive, very rare, and is due to mutations in *CASQ2*-encoded calsequestrin (111,112). Mutations in *KCNJ2*, the same gene for both ATS and SQTs, also may contribute to CPVT (113).

β -Blockers are first-line therapy for patients with symptomatic CPVT. However, because CPVT is more aggressive than LQTS and because β -blockers appear less protective in CPVT compared to LQT1 (105), concomitant therapy with either calcium channel blocking agents (verapamil), flecainide, and/or LCSD should be considered strongly (114–117). An ICD never should be implanted as stand-alone therapy because of the potential for a refractory ICD storm in a CPVT patient whereby the first VF-terminating shock only transiently restores normal sinus rhythm before VF recurs with ultimate failure of the device to restore order.

Brugada Syndrome

The BrS is characterized by typical ECG findings of cove-type ST elevation (type 1 BrS ECG, Fig. 16.2F) in the right precordial leads (V1 to V3) with or without incomplete or complete right bundle branch block, and an increased risk of sudden

death (118). The prevalence of a spontaneous Brugada ECG pattern in the general population is estimated to range from 0.05% to 0.6%. The characterization of a cove-type ST elevation (type I Brugada ECG pattern) or saddle back ST segment elevation (type II Brugada ECG pattern) reflects distinct differences in the risk of sudden death. Overall, the saddle-back-type ST elevation is more common in the general population and far less specific for BrS.

The majority of patients with symptomatic BrS both in Europe and Japan have a cove-type ST elevation (119). The type I Brugada ECG pattern may be present at rest or when unmasked with class I sodium channel blockers including ajmaline, flecainide, or procainamide. Provocative testing with class I agents is used strictly for diagnosis and is of no prognostic value. Superior performance of ajmaline during provocative testing has been demonstrated but this medication is not available in the United States. Increased sensitivity with the resting ECG is achieved by placing the right precordial leads of V1 and V2 in the second intercostal space (Fig. 16.5) (120,121).

Patients more often are male, and often present with SCD due to VF or with syncope due to polymorphic VT. The age of diagnosis ranges from 2 months to 77 years, with a mean of approximately 40 years. Up to 20% of patients diagnosed with idiopathic VF initially may have BrS. An estimated 10% to 20% of patients with BrS also have atrial fibrillation.

In contrast to LQT3 that is due to *gain-of-function* mutations involving the *SCN5A*-encoded cardiac sodium channel $Na_v1.5$, 20% to 30% of BrS is due to *loss-of-function* mutations in *SCN5A* (BrS1) (122,123). To date, over 300 BrS1-causing mutations have been identified in *SCN5A* (124). Over the past 2 years, 10 additional BrS-susceptibility genes: *GPD1L*, *CACNA1C*, *CACNB2*, *CACNA2D1*, *SCN1B*, *SCN3B*, *KCNE3*, *HCN4*, *KCNJ8*, and *KCND3* have been identified (125–134). *GPD1L*-, *SCN1B*-, *SCN3B*-, *KCNE3*-, *HCN4*-, *KCNJ8*-, and *KCND3*-BrS appear to be extremely uncommon (<1% frequency for each) and thus no meaningful genotype–phenotype relationships exist at this point. BrS secondary to dysregulation of the L-type calcium channel complex may be more common (~10%) (126,129). For the most part, there is no apparent difference in clinical outcome for patients with BrS1 versus the majority of patients with *SCN5A*-negative BrS. Patients with BrS1 tend to have longer HV intervals. Patients with BrS1 and a nonsense or frameshift mutation resulting in premature truncations of $Na_v1.5$ exhibit a more severe phenotype (often with concomitant evidence of conduction disease), than patients with a missense mutations (135). Genetic testing is available commercially for BrS1. The *a priori* yield is approximately 25% (50) (www.brugadadrugs.org).

The outcome of patients with BrS depends strongly on the presence of symptoms and the spontaneous presence of a type 1 BrS ECG pattern. In patients who present with aborted sudden death, nearly 66% had documented VF or sudden death in a 4.5-year follow-up period (136). In comparison, only 19% of patients who presented with syncope had VF or sudden death (136). This percentage decreased further to 8% in asymptomatic patients. Therefore, an ICD is indicated for all symptomatic patients (either aborted cardiac arrest or arrhythmic syncope) with BrS (119).

The role of programmed electrical stimulation (PES) for risk stratification of asymptomatic individuals remains unclear (137–140). Proponents of PES–(electrophysiologic study) EPS would advise ICD therapy as primary prevention for asymptomatic patients with inducible VF. Opponents suggest that there is no role for an EPS in the evaluation of BrS. Because BrS-associated events are infrequent in children and adolescents, there is essentially *no* role for an EPS in the *asymptomatic* pediatric patient with only a spontaneous or provoked type I Brugada ECG pattern. Besides ICD therapy for secondary

Figure 16.5. High-lead ECG protocol to unmask a type I Brugada ECG pattern. The type I (coved-type), type II (saddle-back), and type III Brugada ECG patterns are shown in the **upper left panel** with the type I Brugada ECG pattern being most sensitive/specific for the presence of BrS. The high-lead ECG protocol (**bottom left panel**) is used to unmask a type I Brugada ECG pattern shown in **bottom right panel**. After obtaining a standard 12-lead ECG (**left panel**), the right precordial leads V1–V3 are moved up one intercostal space and the ECG is repeated (**middle panel**), and then the V1–V3 leads are moved up another intercostal space and the ECG is repeated (**right panel**). As shown, conversion into a positive type I Brugada ECG pattern is equivalent to a positive drug challenge with agents like ajmaline, procainamide, or flecainide. This simple noninvasive maneuver may be as sensitive as a procainamide challenge although not equal to an ajmaline challenge. Ajmaline is a superior provocative agent but is not available in the United States.

prevention, there may be a role for quinidine in patients with recurrent VF-terminating ICD shocks (141). Aggressive management of febrile illnesses is warranted as fever appears to be an arrhythmic trigger for patients with BrS (142,143).

DISTINGUISHING FEATURES OF “COMMON YET BENIGN” SYNCOPE FROM “SUDDEN DEATH WARNING SIGN” SYNCOPE

It is estimated that approximately half of patients with channelopathies may be asymptomatic and long lived, while the other half will have at least one arrhythmia-mediated cardiac event. For most, that first cardiac event will be arrhythmic syncope with spontaneous resolution (i.e., self-terminating TdP/VF). In contrast to these channelopathies with a combined prevalence of 1 per 1,000, syncope while in normal sinus rhythm (i.e., vasovagal or neurocardiogenic syncope) is extremely common in the general population. Unless there is documentation of the rhythm at the time of the faint, distinguishing the common faint from a potential sudden death warning depends on the circumstances during and surrounding the faint.

Greater than 95% of all syncopal episodes involving otherwise healthy adolescents and young adults are innocuous. Approximately 15% of children and 25% of military recruits (age 17 to 26) have had one syncopal episode (144,145). Syncope will affect up to 20% of males and up to 50% of females by the age of 20, and results in approximately 1 of every 1,200 visits to a pediatric emergency department (144,146,147). However, important cardiac pathology is found in fewer than 5% of children and adolescents with syncope

(148). One of the first population-based studies involving syncope in children and adolescents showed that the incidence of syncope coming to medical attention was between 71.9 and 125.8 per 100,000 population. There was a greater incidence for girls than for boys and the peak incidence was between 15 and 19 years of age (149). In this study, syncope was associated with an acute illness (25%), a noxious stimulus (21%), prescription medication (18%), emotion (12%), bodily function (11%), and/or shower/bath/standing in church (9%). Exertion accounted only for 4% of the syncopal episodes. The vast majority of subjects had a diagnosis of benign vasovagal/neurocardiogenic syncope. Notably, the small subset with a potentially lethal cardiac condition was found among the subjects who fainted during exercise. More recently, investigators from a study involving nearly 500 subjects who fainted concluded that 95% had a noncardiac cause of their syncope, while 3% had LQTS, 1% had another arrhythmia, and 0.4% had a cardiomyopathy (150). An abrupt-onset faint with negligible prodrome that occurred *during* exercise (*not at the conclusion of a SK race*) or during an acute auditory trigger helped to separate those with a sudden death predisposing cardiac condition from the large group of patients with benign syncope.

Although there is only a 3% to 5% chance of important heart disease (i.e., cardiac channelopathy or cardiomyopathy) among all youthful fainters, the pretest probability increases to approximately 35% for a young person with an *exercise-triggered faint*. With an odds ratio > 10 stemming from knowing the patient's history, it is critical that a faint during exercise be viewed as potentially serious. However, it is even more critical to be sure that the faint indeed was exercise-triggered. Here, many *faux pas* have been committed. The history must be gathered carefully. What may initially be described as exercise-associated syncope may, in fact, have occurred after exercise or while the

subject was watching others exercise. An accurate history is extremely important when evaluating a patient who has fainted.

For the patient who truly had a sudden death warning faint, a thorough review of the patient's clinical history and family history is vital. The family history should seek to (a) identify any relatives with similar episodes of unexplained, abrupt onset syncope, (b) identify any relatives diagnosed previously with any form of heart disease, (c) identify any relatives who died suddenly and unexpectedly before the age of 50 years, and (d) identify any relatives who drowned or were involved in single motor vehicle accidents. This should be followed by careful scrutiny of the patient's 12-lead ECG, 24-hour ambulatory ECG, treadmill stress test, and echocardiogram.

Exercise-induced fainting is associated with a 35% chance, not a 100% chance, of an important heart condition. In other words, such a faint does *not* mandate that a diagnosis of a cardiac condition be made. This must be kept in clear view as many of these syndromes have been overdiagnosed seemingly compelled by an obligation to find something wrong with the person who faints during exercise. Benign vasovagal/neurocardiogenic syncope, indeed, can occur "during exercise" but this conclusion must be arrived at only *after* intense investigation.

Even though the vast majority of pediatric patients have a benign mechanism for their syncope, the clinical evaluation of syncope often results in extensive costly testing and possible referral to a pediatric cardiologist for further evaluation (151). In any case of emergency department referral for syncope, especially when cardiac disease is suspected, an ECG is the diagnostic test of choice. If there was a low index of suspicion before the ECG, a normal ECG should probably prompt dismissal from further cardiac evaluation. One must exercise caution when assessing the QTc in the emergency department following a faint that occurred earlier that day. In this setting, the prevalence of borderline QTc values may be even greater because cardiac repolarization may be reacting to the faint rather than suggesting the presence of a substrate responsible for the faint. Previously, we noted that 38% of fainters and 31% of controls had a QTc between 420 and 470 ms that often prompted premature considerations of "borderline" LQTS (152). More recently, a large review of nearly 1,600 patient ECGs obtained in an adult emergency department demonstrated that 35% of patients had a QTc > 450 (males) or > 460 ms (females) (153). The QTc distribution curves shown for otherwise healthy individuals in Figure 16.4 are right shifted among patients seeking medical attention.

Managing the patient who fainted after a prodrome and in the setting of overheating/dehydration, venipuncture/sight of blood, prolonged standing, or during micturition can be vexing. Although not life threatening, these faints are a nuisance for the patient and the family. Although not really a cardiac condition, it often is the pediatric cardiologist who is asked to evaluate these patients. Diagnostic tests should be kept to a minimum. Aggressive hydration (60 to 80 oz of noncaffeinated beverage or until urine is clear) and liberal salt intake often are all that is necessary. Increasing aerobic fitness can help decrease these spells. Drug therapy is entirely trial-and-error, and polypharmacy should be discouraged. Medications tried include β -blockers, vasoconstrictors like midodrine, salt-retaining drugs like Florinef, and selective serotonin reuptake inhibitors.

Electrophysiology Studies and Electrophysiologic Therapeutic Catheterization

J. Philip Saul ■ John D. Kugler

This chapter begins by describing the indications, objectives, and techniques for performing electrophysiologic studies, intracardiac and esophageal, in the pediatric patient without congenital heart disease and pediatric and adult patients with congenital heart disease. These groups are hereafter referred to as *pediatric and adult congenital* when appropriate, where pediatric refers to neonates, infants, children, and adolescents. Following the technical aspects of performing such studies, the use of catheter techniques for arrhythmia therapy in the same group is covered in detail.

ELECTROPHYSIOLOGIC STUDIES—DIAGNOSTIC

Several aspects of electrophysiologic studies in pediatric and adult congenital patients have changed over the past two decades. This chapter emphasizes these changes while reviewing the established age-related and disease-related principles (1–4). The expanding therapeutic use of catheter ablation has had a major impact on various aspects of intracardiac electrophysiologic study, including not only the objectives and techniques during the study but also indications for the study. In addition to the influence of ablation, indications for electrophysiologic studies have changed because of the data from large multicenter studies involving specific arrhythmias and underlying disease processes. Although specific indications for electrophysiologic studies relative to the underlying disease, symptom, or arrhythmia are discussed primarily in other chapters, the objectives are discussed, with emphasis on comparing intracardiac and transesophageal techniques. The advantages and limitations of each technique, as viewed in the context of age, risk/benefit, therapy, and addressing the relevant clinical questions are also addressed.

PLANNING THE STUDY

The clinical questions addressed by the electrophysiologic study should be asked in advance, and the procedure should be planned and guided in this manner. The planning should include choice of intracardiac and/or transesophageal technique, needed preprocedure studies (e.g., electrocardiography [ECG], Holter monitoring, exercise testing, imaging studies); preparation or education of the patient and family; choice of sedation or general anesthesia; preparation of the patient in the procedure room or catheterization laboratory; types of equipment (catheters, sheaths); planned recording, pacing, or ablation protocols (with strategies for each); and administration of provocative or antiarrhythmic drugs. All of these issues are addressed.

INTRACARDIAC TECHNIQUE

Educational and Emotional Preparation of Patient and Family

The importance of patient and family preparation cannot be overemphasized. The potentially long duration of the study, the use of multiple catheters and protocols, and particularly the inclusion of an ablation necessitate relieving patient and family anxiety, which, in turn, enhances patient cooperation. Age-related patient and family preparation begins with the pediatric electrophysiologist and is continued by pediatric cardiac/congenital heart disease electrophysiology nurses. Educational materials can be helpful at all levels.

Sedation and Anesthesia

Sedation is required for virtually all pediatric patients, and most laboratories have transitioned to using general anesthesia or *deep* sedation delivered by an anesthesiologist for all electrophysiologic and nonelectrophysiologic catheter procedures. *Moderate* sedation, in which the patient can still respond when addressed, is generally reserved for older less anxious patients undergoing just a diagnostic or transesophageal electrophysiology study. There has been a shift toward anesthesia over sedation for any electrophysiologic study as dedicated pediatric anesthesia services have become more available.

The pain and discomfort of an ablation procedure does not appear to be very much higher than that for a typical diagnostic catheterization, even accounting for some patients feeling pain during the application of radiofrequency (RF) energy. Thus, general anesthesia is by no means necessary. However, many pediatric electrophysiologists began using general or near general anesthesia for most patients early in the ablation experience for two reasons. First and foremost, uncontrolled patient movement that dislodges the catheter may inadvertently occur at a critical point in the procedure, particularly if the RF application produces pain. One of the authors of this chapter (Saul), in fact experienced an isolated case of complete heart block early in his ablation experience that occurred in part from untimely movement of an uncooperative patient during ablation of a midseptal accessory pathway (AP) (5), leading the Children's Hospital in Boston to replace heavy, often disorienting sedation with general anesthesia for most patients. Second, most centers have found that even older cooperative children and young adults find a long procedure much more tolerable under anesthesia and are more willing to return for follow-up procedures, when needed. Currently, virtually all pediatric electrophysiologists use general anesthesia for ablation procedures.

Figure 17.1. Diagram showing the major components of an electrophysiology (EP) cardiac laboratory (lab). An EP lab can be configured using equipment from several companies. In this illustration, the Prucka CardioLab System (General Electric Healthcare, UK) is interfaced with the electronic stimulator. Together, they provide the system by which conventional electrogram recordings are displayed and pacing protocols are performed and recorded. A 3-D mapping system can interface with the conventional system to enhance mapping (see text) and minimize use of fluoroscopy. In this example, the EnSite NavX (St. Jude Medical, St. Paul, MN) provides the ability to view nonfluoroscopic images (see Fig. 17.5) of the catheter positions at the EnSite Workstation also with simultaneous conventional electrogram recordings. As is shown in Figure 17.5, much greater detailed 3-D mapping images can be generated using the intracardiac balloon/electrode array EnSite system. Integration of preprocedure cardiac magnetic resonance images or computed tomographic images can be downloaded and interfaced into the 3-D recording system.

Sedation and anesthesia agents generally are not standardized in electrophysiology laboratories, with multiple appropriate regimens used; however, there are a few common themes. In general, anticholinergic agents should be avoided because of their electrophysiologic effects. These include agents like chlorpromazine and the drying agents atropine and glycopyrrolate. Most sedative regimens include a narcotic (e.g., meperidine, morphine, or fentanyl) for pain and benzodiazepines for sedative amnesia (e.g., diazepam or midazolam). Midazolam may be a better choice than diazepam because of its demonstrated lack of electrophysiologic effect (6,7). Antiemetics like phenergan or droperidol are acceptable, if necessary, but preferably avoided. Continuous intravenous propofol has gained increased acceptance as a deep sedative at lower doses and as a general anesthetic at a higher dose (8). With propofol's low incidence of postprocedure nausea and vomiting, patients recover faster with less lingering sedation, and because of the decreased vomiting, Valsalva-related catheter site bleeding is minimized. The electrophysiologic effects of propofol in children appear to be minimal and similar to isoflurane-based anesthetics (9).

Preparation of the Patient in the Catheterization Laboratory

Initial patient preparation involves positioning and then comforting the patient on the table. When a long procedure is planned, securing the arms above the shoulders may promote the undesired complication of brachial plexus injury. Although positioning the arms inferiorly along the thorax interferes with the straight lateral fluoroscopy view, rotating slightly to 10 to 20 degrees right anterior oblique (RAO) with the anterior-posterior tubes and 80 to 70 degrees left anterior oblique (LAO) with the lateral tubes alleviates this problem while still providing acceptable views for catheter introduction. All limb and chest surface ECG leads are placed initially, allowing for a choice of displayed leads. Selection of a displayed lead is based on the underlying arrhythmia or conduction disturbance. When a contemporary digital recording system is used, a full 12-lead ECG is available at any time regardless of the fewer displayed leads.

Many pediatric electrophysiologists now use 3-D mapping systems. Depending on the system used, the initial room setup and preparation of the patient involves steps that are required for proper functioning of the system (e.g., pads placed/positioned, connections, and interfacing as illustrated in Fig. 17.1). Routine use of the disposable (and translucent) defibrillation pad and lead system has improved cardioversion and emergency defibrillation efficiency and probably has improved the safety of the intracardiac study.

Sheath and Catheter Placement

In patients undergoing electrophysiologic study, special care is needed when infiltrating skin and subcutaneous areas with lidocaine (1–4). Studies have shown that therapeutic and, therefore, antiarrhythmic serum concentrations have been achieved with routine use of 2% lidocaine (10). One percent or, ideally, 0.5% concentration given in sufficient amounts to achieve local anesthesia, but not in increased volume, is recommended to avoid therapeutic lidocaine serum concentration.

The number, size, and location of the sheaths relates to the age and size of the patient, the underlying arrhythmia, and objectives of the study. In most studies, the number of sheaths varies between one and five, with the maximum number consisting of three in the femoral veins, up to two in the internal jugular vein, and one in the femoral artery. Sheath sizes usually correlate directly with the size of the patient and vary between 4 and 8 French (Fr). The 7 or 8 Fr sheaths are helpful when intravenous drug administration is required because a side-arm sheath larger than the catheter permits free, unobstructed flow of fluid into the vein. In addition, some ablation catheters have larger tips and require an 8 Fr sheath for introduction.

The ultimate number and location of the sheaths also depend on the success of catheter manipulation and preference of the operator. For example, the coronary sinus (CS) catheter can be advanced from the inferior or superior vena cava. From the inferior caval approach, a catheter can be manipulated into the CS from the femoral vein/inferior vena cava (IVC) by looping the catheter in the right atrium or by directly advancing it from the right atrium (2,3). If this is either not successful or not desirable, a sheath or catheter can be advanced from the superior vena caval approach. This is accomplished from the arm (the median basilic vein in the left arm is preferred), neck (either internal jugular, but right is preferred), or subclavian vein (either right or left) approach (2,3). A limitation to the arm approach is that the arm is extended throughout the procedure, which can be uncomfortable to the patient and can interfere with the lateral fluoroscopy tube positioning. An advantage to the internal jugular vein is that its larger size can more easily accommodate a second sheath if needed (e.g., in a patient such as the one shown in Figure 17.2, in whom a mapping or ablation catheter is manipulated from above to reach a location along the tricuspid annulus not accessible from the femoral approach).

Although not mandated, to enhance safety a femoral artery cannula allows access to monitor arterial blood pressure continuously throughout the procedure. When a sheath is placed in the femoral artery for retrograde access to the left ventricle, a side-arm sheath one size larger than the catheter permits accurate pressure recordings. Otherwise, a small plastic cannula/dilator is used.

The use of anticoagulation to minimize thromboembolic complications varies among laboratories and is difficult

Figure 17.2. Right anterior oblique (RAO) and left anterior oblique (LAO) single-frame radiographs (top) from biplane cine with accompanying diagrammatic illustrations (bottom) showing multiple-electrode catheter positions during an intracardiac electrophysiologic study in a 6-year-old boy with WPW syndrome (right anterior septal accessory AV pathway). **A:** The RAO view (anterior–posterior tubes rotated 45 degrees) provides the operator with a direct anterior–posterior view (right to left, respectively, as viewed in the radiograph and illustration), with the AV valves nearly perpendicular to the operation. **B:** The corresponding LAO biplane view (lateral tubes rotated 45 degrees) provides the operator with a direct left–right view (tricuspid valve annulus on left and mitral valve annulus on right, with septal area between). Note that three 6 Fr catheters were advanced from the femoral veins and positioned in the high right atrium (HRA), right atrial appendage (RAA), right ventricular apex (RVA), and His position. Two 6 Fr catheters were advanced from the right internal jugular vein and positioned in the coronary sinus (CS) posterior to the mitral valve (MV) annulus and under the tricuspid valve (TV) leaflet anterior (ant. septal) to the His catheter where the accessory AV pathway (AP) was located. The tricuspid valve annulus and the mitral valve annulus are depicted in positions predicted by the catheter positions to demonstrate approximate locations. The surface electrocardiographic leads and skin electrodes, as well as RF and defibrillation skin pads, are not labeled. (See Fig. 17.8 for recordings from these electrode catheters in this patient.)

to analyze because it is difficult to separate the diagnostic procedure from the various interventional procedures (catheter ablation and the techniques used for ablation). Zhou et al. (11) reviewed the literature to show that heparin use does not eliminate the risk of thromboembolic complications during RF catheter ablation. Anfinssen et al. (12) in a randomized study in adults showed that heparin administration immediately after sheath placement significantly decreased hemostatic activation. In a separate study, these investigators also showed that the procedure duration prior to heparin administration determined

hemostatic activation and fibrinolysis independent of RF ablation (RFA) (13). Tse et al. (14) found both platelet and coagulation activation during RFA, but platelet activation was not found during cryoablation. The heparin dose varies among laboratories, but the initial dose is usually 70 to 100 U/kg, to a maximum of 5,000 U. Ongoing heparin anticoagulation can be provided by a continuous intravenous infusion (e.g., 15 to 20 U/kg/h) or by boluses. To follow the degree of optimal anticoagulation during long procedures, the activated clotting time (ACT) is measured one to three times per hour to achieve a desired

value of 200 to 300 seconds, except when a 3-D balloon array mapping system is used within the left atrium or ventricle and an ACT of >300 seconds is desirable. For typical studies, most laboratories administer 100 U/kg of heparin after all the sheaths are in, monitor the ACT every 30 to 60 minutes, and give additional boluses of heparin to keep the ACT >200 seconds.

Electrode Catheters

The catheter sizes vary from 2 to 7 Fr. Traditionally, 4 Fr catheters were used virtually only for infants, whereas 5 Fr catheters most often were used in young children, and 6 and 7 Fr catheters were used for adolescents and adult-sized patients. Smaller (2 to 3 Fr) catheters can be used for intracardiac recordings as well as for epicardial mapping (by advancing the catheters from the CS into the very small branches throughout the epicardial surface) (15). These small catheters may be used in small children to record intracardiac electrograms throughout the conduction system. Although these small catheters may be difficult to manipulate, up to three catheters can be used in the same sheath. Also, 2 Fr active fixation catheters (e.g., Medtronic, Inc.) can be used in patients such as those with preexcitation/Wolff-Parkinson-White (WPW) syndrome who undergo a single-catheter short-duration study to assess risk of rapid A-V conduction of atrial fibrillation. These small catheters can be used in any size patients with the advantage of minimizing the venous puncture site—and therefore skin, muscle, and vein trauma—allowing quick recovery with low groin morbidity.

Catheter electrodes vary in number and interval distance. Traditionally, catheters used for recording and pacing were in a quadripolar configuration, whereas catheters used primarily for recording and mapping contain between 6 and 12 electrodes. However, currently, catheters with 6 to 10 electrodes often are used for multiple purposes, such as recording/mapping in the CS and atrial pacing. Similarly, some catheters are designed to record atrial and His potentials from proximal electrodes, while distal electrodes are used to pace the ventricle. Specially formed catheters also are available for the His location with an “S” shaped tip providing stable seating between the anterior and septal tricuspid leaflets. These catheters tend to work best in larger pediatric patients. Short (1 to 2 mm) interelectrode distances for the bipoles, separated by 5 to 10 mm spacing allow high quality electrograms and precise mapping, while spanning a larger region of the heart.

The number of catheters used during a study depends not only on the size of the patient and the underlying problem but also on whether the electrophysiologist prefers the minimum or maximum possible amount of catheter manipulation during the study. If the least amount of catheter manipulation is desired, more catheters are positioned initially, and these are left in place for the duration of the procedure. Electrophysiologists who use more catheters prefer the advantage of simultaneous recording from the multiple catheters to optimize data collection. If multiple changes in catheter positions are deemed acceptable, fewer catheters initially are placed. Use of fewer catheters requires moving the catheter from one area to another and perhaps back to the original position during the study. However, it may not be possible without using mapping systems (described later, e.g., the NavX system, St. Jude Medical, Minneapolis, MN, and shown in Fig. 17.3) to return the catheter to the precise original location, and electrogram consistency may be compromised or the arrhythmia affected by the catheter movement (e.g., arrhythmia may not be inducible thereafter, so optimal gathering and recording of information is lost). Also, with each catheter position change, the otherwise satisfactorily sedated patient may become disturbed, in the absence of anesthesia.

Manipulation and placement of electrode catheters involves several factors, including patient size and age, underlying

arrhythmia, objectives of the individual study, size and type of catheters (e.g., steerable), and underlying cardiac and blood vessel anatomy.

Catheter access to the left atrium or ventricle is desirable for several reasons, usually for the purpose of recording and stimulation of the left atrium and ventricle for evaluation and mapping of supraventricular tachyarrhythmias. With increasing use of catheter ablation, left-sided APs or ectopic arrhythmia foci require catheter access to the left side. The location of the CS provides precise mapping of APs along the mitral valve annulus. For left-sided atrial and ventricular ectopic foci and for ablation catheter manipulation, a lone catheter within the CS is insufficient. This has prompted use of the retrograde arterial approach or the transseptal approach via a patent foramen ovale or a transseptal needle and sheath (Brockenbrough) technique. Limitations are associated with each technique (2,16).

Biplane (rather than single-plane) fluoroscopy is not essential but becomes more critical as the procedure becomes more complicated. It helps minimize the risk of perforation and enhances procedural efficiency, while maximizing the precision of catheter manipulation during mapping. For mapping, especially when it involves the tricuspid annulus, mitral annulus, and posterior septal area, the positioning of the fluoroscopy x-ray tubes in a perpendicular alignment to the long and short cardiac axes optimizes recognition of anatomic relationships (Fig. 17.2). This involves rotation of the anterior-posterior tubes to approximately 30 degrees RAO position and the lateral tube perpendicular at about 60 degrees LAO position. In addition, 10 to 15 degrees of caudal angulation of the LAO tube provides a view directly orthogonal to the mitral annulus, facilitating mapping of left-sided APs (Fig. 17.4).

Recording and Stimulation Technique

The display and recording of the intracardiac electrograms are undertaken after catheter placement. Most electrograms are displayed and recorded in a bipolar fashion, although unipolar electrograms are obtainable easily and can be helpful for mapping arrhythmia foci (17). Various recordings and stimulation systems are commercially available, and some laboratories customize systems. Most laboratories use a digital computer-based system that maximizes recording and stimulation efficiency by eliminating manual switching of catheter connections, eliminating paper recordings, providing a database/reporting system, and providing online measurements with freeze-scope capability (Fig. 17.1). The 3-D mapping systems, used primarily when ablation is planned, incorporate the temporal and spatial (anatomic) details and therefore provide much more precise diagnostic data (see Interventional section for more details) (18). Also, many 3-D systems have the capacity to capture continuous rhythm for analysis when sustained tachyarrhythmias are not inducible or when the arrhythmia is associated with intolerable hemodynamics. The 3-D mapping systems have added an important diagnostic component to electrophysiologic studies and also have provided increased safety by decreasing radiation exposure because catheter manipulation can be performed without, or by minimizing, fluoroscopy (19,20). Regardless of the specific 3-D system used, Packer (18) summarizes the minimal general requirements as follows: (i) accurately replicate the cardiac anatomy underlying the arrhythmia, (ii) provide a plausible representation of activation of that chamber, as linked to the specific anatomic site of data acquisition, (iii) readily capture and intelligibly display other details of physiology, and (iv) catalogue the site of interventions. These features are illustrated in Figures 17.5 to 17.7.

A standard method or order of electrogram display and recording on the optical disk monitor does not exist, but typical

Figure 17.3. Two recordings in a 3-year-old boy with incessant, fast (220-ms cycle length; rate 272 beats per minute), orthodromic reciprocating AV reentrant SVT that demonstrate the advantage of fast recording speed. **Left:** Using a recording speed of 100 mm/s, the earliest retrograde (conduction via posterior septal accessory AV pathway) atrial activation was difficult to determine. The atrial activation closest to the vertical line appeared to be either from the distal pair of electrodes on the tricuspid valve annulus mapping catheter (TVD) located at the posterior septal area or from the proximal pair of electrodes on the coronary sinus (PCS) catheter, located approximately 0.5 cm into the CS from the os. **Right:** By doubling the recording speed to 200 mm/s, the earliest electrogram not only appeared to be more easily detected by the TVD electrodes but also the low-amplitude earliest electrogram appeared to be from the accessory AV pathway (see also Fig. 17.3). (Other abbreviations are as described in Fig. 17.8).

examples are illustrated in Figure 17.8. It is advantageous to record at least three or four simultaneous surface ECGs, including two perpendicular limb leads to elicit P or QRS frontal plane axis changes and one or two chest leads to maximize detection of bundle branch changes. A major effort should be undertaken to record a His bundle electrogram (HBE). Virtually all mechanisms of arrhythmias and conduction system disturbances are definitive only when an HBE is recorded. When the usual catheter position (superior or septal tricuspid valve annulus) fails to elicit an HBE, advancing a catheter retrogradely to

the noncoronary aortic sinus can allow successful recording. With catheters used for both recording and stimulation, the distal pair of electrodes is best suited for pacing consistency, and all proximal pairs are then used for recording. Because of fast tachycardia rates in children, fast recording capability (200 mm/s or higher) is essential to differentiate electrograms recorded by the various electrode catheters (Fig. 17.3).

The pacing and recording protocols used are variable, and emphasis should be on flexibility and patient-specific diagnosis and findings. The specific protocols chosen should be adapted to

Figure 17.4. Catheter projections for ablation procedures. Note how left anterior oblique (LAO) view plus caudal angulation maximally elongates the mitral annulus. (From Saul JP, Hulse JE, DeW, et al. Catheter ablation of accessory atrioventricular pathways in young patients: use of long vascular sheaths, the transseptal approach and a retrograde left posterior parallel approach. *J Am Coll Cardiol* 1993;21:571-583, with permission.)

Figure 17.5. This figure shows the use of the EnSite 3-D intracavitary balloon noncontact mapping system (St. Jude Medical, St. Paul, MN). (A, top left) Fluoroscopic RAO image is shown: (1) wire in main pulmonary artery placed to enable advancing the balloon/mesh catheter, (2) 64-electrode mesh inflated balloon in the right ventricular outflow tract (RVOT), (3) mapping/ablation catheter in RVOT, (4) high right atrial catheter, (5) retrograde mapping/ablation catheter in aortic root/sinus, (6) His catheter, and (7) RV apex catheter. (B, top middle) Picture of mapping balloon shows a grid of wires criss-crossing the surface of the balloon, creating 64 individual electrodes. (top right) A computer reconstruction of the right atrium (CSO, coronary sinus os; APP, appendage) showing the endocavitary location of the balloon and voltages on the endocardial surface at a single point in time. Activation is currently septal, shown by the white color above the CSO. (Bottom Panels) Right atrium during intra-atrial reentry tachycardia (IART) in a 14-year-old boy after an atriopulmonary Fontan operation. The torso shows these are slight RAO projections. The atrium is large and bulbous. Although a little fuzzy, an area of presumed block secondary to a right lateral atrial scar is shown by a dark line along the anterolateral RA. When played as a movie the tachycardia proceeded around the scar inferior to superior on the anterior surface and superior to anterior on the posterolateral. The two images show posterior activation on the left and lateral activation on the right. The image of the balloon can be seen within the chamber.

the patient as they relate to the preprocedure diagnosis, but they also should remain flexible during the study, dependent on ongoing elicited findings. It is beyond the scope of this chapter to provide examples of protocols for each specific type of arrhythmias and conduction disturbances. Most can be found either elsewhere in this chapter or in the literature (2–4,16,21–23). However, in Table 17.1, a list of pacing protocols provides examples of options used during intracardiac studies. Also, with the advent of catheter ablation and with the advances in 3-D mapping technology, the techniques and objectives of mapping have assumed a major new role and are emphasized in the interventional section of this chapter. The important general mapping concepts include the fluoroscopic image, catheter manipulation techniques, various modes of pacing, nuances of electrogram recordings, and 3-D mapping (Figs. 17.1–17.4,17.8,17.9, Figs. 17.5–17.7).

Administration of Drugs

Intravenous drug administration during an intracardiac study encompasses three general categories: anesthetic drugs, provocative arrhythmic drugs, and antiarrhythmic drugs. Of the three, anesthetic drugs are the most commonly administered and were discussed earlier in this chapter. The most commonly used provocative arrhythmic drug is isoproterenol. Other less frequently used provocative drugs include epinephrine, atropine, aminophylline, phenylephrine, procainamide, or flecainide (for Brugada syndrome) (2,3,24–28). Because of sleep- or sedative-induced vagotonia, one of these provocative drugs may be necessary to induce or sustain tachycardia, which is essential to determine arrhythmia mechanisms and the site of arrhythmia foci or pathways. Also, some arrhythmias can be observed only

Figure 17.6. When imaging of multiple-catheter location is desired with or without the need for anatomic imaging detail, a mapping system such as NavX (St. Jude Medical, St. Paul, MN) or the latest fast mapping version of Biosense CARTO can be used. As shown in this image of the left and right atria, all the catheter locations can be seen. The CS catheter is under left atrium in *green*, and an ablation catheter can be seen in the right middle pulmonary vein through the right atrium. The torso shown in this is an LAO view. The system provides the ability to reflect real-time motion of catheter position, minimizing use of fluoroscopy and radiation exposure (see text). In addition, the catheters can be used to derive “geometry” by sequential positioning of any of the catheter electrodes at multiple sites along the endocardial chamber. With the new Velocity system shown here the geometry can be made out of multiple segments to create a realistic 3-D model of cardiac structures. This image is also improved by merging the catheter-acquired data with a CT image. Once the geometry is made, modifications like “cutting out” the tricuspid and mitral valves can be added, as shown here. Then signals can be acquired from any catheter electrodes and timing points derived to make a timing map. The timing map shown here is in the left atrium with early activation in *pink red* in the low lateral left atrium, probably near the left lower pulmonary vein. Activation proceeds anteriorly and superiorly to *yellow* and *blue* colors. The ECG and electrograms at the bottom include a window (*right lower*) that demonstrates where in the cardiac cycle the colors in the image correspond to. Although not shown in this patient, the location of ablation lesions or other points of interest can be easily added. (With permission from St. Jude Medical, St. Paul, MN.)

when the heart rate is lower or are observed better in the presence of second-degree AV block (e.g., atrial reentry tachycardia), situations where enhanced vagotonia is helpful and can be induced by an infusion of phenylephrine titrated to moderately

raise arterial pressure. The doses of isoproterenol and epinephrine continuous-drip infusions are similar and range from 0.01 to 0.1 $\mu\text{g/kg/min}$. Atropine (0.01 to 0.04 mg/kg) is used infrequently because it cannot be administered as a continuous drip

Figure 17.7. AP potentials. The first four signals are surface ECG leads. The second two come from the mapping/ablation catheter. Note that there is minimal preexcitation in the surface leads pre-ablation; however, a very large potential is seen in the distal electrode pair of the mapping catheter (*arrow*) preceding the surface QRS. This probable AP potential is no longer present after the ablation. (From Saul JP, Hulse JE, De W, et al. Catheter ablation of accessory AV pathways in young patients: use of long vascular sheaths, the transseptal approach and a retrograde left posterior parallel approach. *J Am Coll Cardiol* 1993;21: 571–583, with permission.)

Figure 17.8. Three recordings in a 6-year-old boy (same patient as in Fig. 17.2) with preexcitation owing to a right anterior septal accessory AV pathway showing baseline sinus rhythm (A), orthodromic reciprocating AV reentrant SVT (B), and sinus rhythm after successful RF catheter ablation (C). In each plot, the four recordings from surface ECG leads are displayed at the top, followed by intracardiac recordings. The electrograms from the proximal two electrodes on the quadripolar catheter in the high right atrium (HRA) are followed by the proximal (HBEP), middle (HBEM), and distal (HBED). HBEs from the hexapolar catheter positioned across the anterior septal area of the tricuspid valve. Recordings from this His bundle location elicit activity in the low atrium (best recorded by the HBEP), the His bundle (best recorded by the HBEM or HBED), and the anterior septal inflow area of the right ventricle (best recorded by the HBED). In (A), note that the presence of preexcitation from an anterior septal accessory AV pathway eliminated the ability to record an HBE because the septal right ventricular myocardium was activated first by conduction through the accessory AV pathway. The HBE was recorded later, during SVT, when antegrade conduction existed through the His (H) bundle alone (retrograde conduction was via the accessory AV pathway) and after successful ablation (B and C, respectively) slightly anterior to the His bundle catheter location. This is shown best by the low-amplitude, almost continuous electrogram between the atrial and ventricular electrograms recorded by the distal electrodes (TVD). The electrograms recorded by the proximal, middle, and distal pairs of electrodes on the hexapolar catheter in the CS are designated PCS, MCS, and DCS, respectively. The next recording was from the proximal pair of electrodes on the quadripolar catheter in the right ventricular apex (RVA). The femoral arterial pressure (FAP) is displayed below.

and because of its longer-lasting effects. Phenylephrine can be given as a bolus of 0.50 to 1.0 $\mu\text{g}/\text{kg}$ and titrated as an infusion to the desired blood pressure.

Before the ablation era, antiarrhythmic drug administration during intracardiac electrophysiologic study commonly was used to assess drug safety and efficiency of planned chronic therapy

(29). Although chronic medical therapy still exists as a treatment option (especially for patients with ventricular arrhythmias), its use is declining because of the increased application of ablation treatment and cardioverter-defibrillator device options.

Antiarrhythmic drug administration also is used commonly to achieve acute effects. This is indicated most often in an

TABLE 17.1 Pacing Protocols for Intracardiac Electrophysiologic Study

1. Sinus node function
 - a. Sinus node recovery time
 - b. Sinoatrial conduction time
2. AV conduction
 - a. Continuous atrial decremental pacing
 - b. Premature atrial extrastimulus technique (during sinus and/or eight-beat drives of a-paced rhythm)
3. VA conduction
 - a. Continuous ventricular decremental pacing
 - b. Premature ventricular extrastimulus technique (during sinus and/or eight-beat drives of v-paced rhythm)
4. Atrial muscle conduction and refractory period
 - a. Premature atrial extrastimulus technique (during sinus and/or eight-beat drives of a-paced rhythm)
5. Ventricular muscle conduction and refractory period
 - a. Premature ventricular extrastimulus technique (during eight-beat drives of v-paced rhythm)
6. Induction of SVT
 - a. One or more of the following: Continuous atrial decremental pacing (or short bursts), premature atrial extrastimulus technique (using one or more drive cycle lengths, one to three extrastimuli, and one or more pacing sites such as HRA, LRA, CS), continuous ventricular decremental pacing, premature ventricular extrastimulus technique (during sinus and/or eight-beat drives of v-paced rhythm)
 - b. If unsuccessful, add provocative drug and repeat step 6a
7. Determine SVT mechanism, map location
 - a. Results of steps 6a, b
 - b. One or more of the following during underlying SVT rhythm with use of recording electrodes in several locations pertinent to type of tachycardia: Premature atrial extrastimulus technique (from one or more pacing sites such as HRA, LRA, CS), premature ventricular extrastimulus technique (from one or more pacing sites such as RV, LV)
8. Risk stratification in asymptomatic or symptomatic WPW
 - a. Premature atrial extrastimulus technique (using one or more drive cycle lengths, one or more pacing sites such as HRA, LRA, CS) to determine the antegrade effective refractory of the AP
 - b. Continuous atrial decremental pacing (or short bursts) to determine minimum cycle length for 1:1 conduction in the AP
 - c. Attempted induction of SVT as in steps 6a,b, and determine mechanism as in step 7
 - d. Premature right ventricular extrastimulus technique (using one or more drive cycle lengths) to determine the presence of retrograde conduction and the effective refractory of the AP.
 - e. Attempted induction of atrial fibrillation to determine the minimum preexcited RR interval during atrial fibrillation.
9. Induction of ventricular tachyarrhythmia
 - a. One or more of the following: Continuous ventricular decremental pacing (or short bursts), premature ventricular extrastimulus technique (using one or more drive cycle lengths, one to four extrastimuli, and one or more pacing sites such as RVA, RVOT, LV), continuous atrial decremental pacing, premature atrial extrastimulus technique (during sinus and/or eight-beat drives of v-paced rhythm)
 - b. If unsuccessful, add provocative drug and repeat step 8a
10. Determine VT mechanism, map location
 - a. Results of steps 8a, b

AV, atrioventricular; VA, ventriculoatrial; HRA, high right atrium; LRA, lower right atrium; CS, coronary sinus; SVT, supraventricular tachycardia; RV, right ventricle; LV, left ventricle; RVA, right ventricular apex; RVOT, RV outflow tract; VT, ventricular tachycardia.

attempt to block atrioventricular (AV) nodal conduction. The AV nodal blocking effects of verapamil, esmolol, propranolol, adenosine, or phenylephrine (as discussed above) are helpful to elucidate arrhythmia mechanisms and to distinguish the type of AV and ventriculoatrial (VA) conduction, if present (30–32).

Complications

Complications have been reported and analyzed for nonelectrophysiologic cardiac catheterizations in children (33–38). Only the 1998 report by Vitiello et al. (37) and the summary in a previous edition of this book by Kugler (16) have separate analyses of electrophysiologic studies. Vitiello et al. (37)

conducted an extensive statistical analysis (stepwise multiple logistic regression followed by categorical variable testing of models, which was further tested by Hosmer-Lemeshow's goodness of fit) of 4,952 consecutive cases (3,149 diagnostic, 1,371 interventional, 383 electrophysiologic, 41 ablation). Electrophysiologic procedures had the lowest rate of major complications at 0.7%, similar to the 0.8% of diagnostic procedures, and both were less than the interventional (ablations included in interventional) rate of 2.0%. An electrophysiologic study was not an independent risk factor for a complication. However, because ablation was included as an interventional procedure, it was an independent risk factor for complication during electrophysiologic study. It appears that addition of an ablation procedure increases the risk of

FIGURE 17.9. Three recordings from the same patient as in Fig. 17.10 demonstrating the recording of an electrogram from an accessory atrioventricular (AV) pathway (AP). **A:** During orthodromic reciprocating AV reentrant SVT (220-ms cycle length, same recording as in Fig. 17.3), an early, low-amplitude electrogram (arrow, AP) was recorded before a biphasic electrogram that appeared to be either a fusion with the following atrial (A) electrogram or a biphasic atrial electrogram. H, His bundle. **B:** During ventricular pacing (500-ms cycle length), a virtually identical electrogram was recorded (arrow, AP). **C:** During ventricular pacing at the same cycle length after successful RF catheter ablation, the AP electrogram was eliminated (arrow). Also, after the ablation, normal retrograde conduction was verified by several other pacing protocols (not shown). (Other abbreviations are as described in Fig. 17.8.)

the procedure to a level similar to that of other interventional catheter procedures (16). For the Pediatric Electrophysiology Society's catheter ablation registry, Schaffer et al. (39) studied the mortality rate and found a mortality rate of 0.12% for all procedures and a correlation of mortality with underlying heart disease (increased to 0.89%), greater number of energy applications, left-sided procedures, and lower body weight. The latter risk factor also was found in the single-center report of Rhodes et al. (38) for patients ≤ 5 kg, but they included only nonelectrophysiology catheterization procedures.

TRANSESOPHAGEAL TECHNIQUE

This section covers both the *isolated* transesophageal study, as well as one performed as a preliminary study for supraventricular tachycardia (SVT) inducibility or WPW syndrome risk stratification prior to a possible catheter ablation procedure. The primary difference is that sedation might be replaced by general anesthesia if an ablation is being considered to immediately follow the transesophageal procedure.

Educational and Emotional Preparation of Patient and Family

The preparation of the patient and family for a transesophageal study centers on explaining the technique and addressing expectations and concerns related to placement of the catheter followed by pacing and stimulation. Educational materials

backed by an honest but positive and confident approach during the explanation session are important in successfully achieving the goals of a transesophageal study in an older child or adolescent. In infants and small children, the same approach is modified and directed toward the parents.

Sedation

If general anesthesia is not being used as described above, mild to moderate sedation usually is sufficient to maximize patient cooperation while relieving discomfort and anxiety. For infants, children, and adolescents, intravenous midazolam (0.05 to 0.1 mg/kg) with morphine (0.05 to 0.1 mg/kg) or fentanyl (1 to 2 μ g/kg), is an effective analgesic/amnestic sedative combination. Before a peripheral intravenous line is established, oral diazepam (0.2 to 0.4 mg/kg) or intranasal midazolam (0.2 to 0.3 mg/kg) can also be used to control anxiety and thereby allow the patient to be more cooperative (40).

Preparation of Patient in the Procedure Room

Whether in an inpatient or outpatient setting, the transesophageal technique easily is adaptable to virtually any type of room or location where the patient can be comfortably supine and where sufficient space exists for equipment and monitoring. After peripheral intravenous access is established, the surface ECG leads are placed and connected. A direct current (DC) defibrillation and cardioversion system should be available, or chest pads can be placed routinely, as with most intracardiac studies. Sedation is administered as needed with appropriate

vital sign (heart rate, respiratory rate, and blood pressure) and oximetry monitoring protocols established. In most infants and children, comfortable extremity restraints are necessary to prevent withdrawal of the catheter by the patient. The success of a transesophageal study depends highly on a positive, encouraging approach during the procedure by the pediatric electrophysiologist, pediatric cardiology nurse, and associated personnel. A soothing, comforting manner is necessary for successful passage of the catheter, as well as for successful recording and stimulation because of the potential mild discomfort encountered during each of these steps.

Catheter Placement

Similar to passage of a nasogastric tube, initial placement of the catheter involves lubrication (KY type jelly usually is sufficient, but local lidocaine gel can be beneficial). Entry through the nares is followed by firm but gentle advancement through the posterior pharynx into the esophagus. Encouragement of repeated swallowing by the awake patient facilitates the catheter placement. The distance of catheter advancement required to reach the predicted area best suited for recording and pacing directly correlates with patient height (41) (Fig. 17.10). However, this predicted depth may not actually be the ideal location and minor adjustments may be necessary. The optimal catheter electrode position for pacing correlates with the largest atrial electrogram amplitude. Short distances (a few millimeters) of catheter withdrawal and advancement are performed until the maximum atrial electrogram amplitude is found. The catheter is then secured by taping it to the patient's face or nose.

Equipment and Recording/Stimulation Technique

The three major equipment components are the electrode catheter, the recording apparatus (monitor, strip-chart recorder), and the stimulator (Fig. 14.8). Successful transesophageal

Figure 17.10. Graph of depth of transesophageal electrode catheter insertion (measured from distal electrode on catheter) from the nares in pediatric patients of various heights. By plotting the patient's height, in centimeters, the correlating distal electrode depth can be determined. After the distal electrode has been positioned at the predicted depth, small adjustments may be necessary for optimal recording and pacing. (From Benson DW Jr, Sanford M, Dunnigan A, et al. Transesophageal atrial pacing threshold: Role of interelectrode spacing, pulse width and catheter insertion depth. *Am J Cardiol* 1984;53:1102-1106, with permission.)

recording and stimulation in infants, children, and adolescents have been reported with various types of electrode catheters. Transesophageal electrode catheters differ in size (4 to 10 Fr), interelectrode distance (2 to 30 mm), and number of electrodes (bipolar, quadripolar, hexapolar). Although the adult "pill" electrode can be used in the older child and adolescent, the electrode catheter is better suited for the pediatric patient. Moreover, some transesophageal catheter manufacturers have been receptive to customized catheter design regarding electrode number and interelectrode distance. Benson et al. (41) found that the interelectrode distances (12, 22, and 28 mm) had no significant effect on pacing thresholds regardless of age or size of the patient. Essentially no data are available that compare catheter sizes in pediatric patients; however, intuitively, if electrode contact with the esophageal wall is an important goal, the largest possible catheter size should be used. In normal-sized newborn infants, the nares easily accommodate catheters in the 5 to 7 Fr range; however, a 10 Fr catheter can be placed through the mouth if there is difficulty with the smaller catheter in the nares. In older children and adult-sized adolescents, 10 Fr catheters are used most often. Bipolar electrode configuration limits the technique to either recording or pacing, so quadripolar electrode catheters have been designed to permit simultaneous pacing and recording, with the recording interelectrode distance shorter (2 mm) than the pacing interelectrode distance (12 to 30 mm). Most catheters used today are bipolar.

The recording equipment consists minimally of a strip-chart recorder with an ECG monitor. Without a monitor, the strip-chart recorder can run continuously and, therefore, also functions as the monitor. The recording system can be set up in a unipolar or bipolar fashion (Fig. 17.11). When possible, performing the procedure in the intracardiac EP laboratory allows use of the same digital recording system used for more complex studies, with all its inherent advantages and standard signal filtering capabilities.

A unipolar recording system is the simplest and involves the lowest investment in equipment because a preamplifier is not required. A three-channel ECG machine can function as both a strip-chart recorder and monitor (Fig. 17.11). A three-channel simultaneous-recording ECG machine uses one channel for a unipolar esophageal lead and the other two channels for two surface ECG leads. For example, the V1 chest lead is connected to one of the electrodes on the transesophageal catheter. The recordings from the V2 and V3 chest leads are then displayed or recorded simultaneously to permit comparison of the QRS and P waves on the surface leads with the electrograms from the unipolar esophageal lead (Figs. 17.11A and 17.12). Alternatively, two simultaneous unipolar esophageal electrograms, each from a separate esophageal electrode, can be displayed or recorded with the recording from one surface ECG lead. Recording during pacing is carried out either without the simultaneous transesophageal electrogram, by reconnecting the V1 chest lead to the V1 skin lead as illustrated in Figure 17.13, or with the simultaneous recording from a transesophageal lead (Figs. 17.11B and 17.14).

A bipolar system has the advantages of more reproducible and reliable atrial electrograms. The baseline wanders less, and the atrial electrograms are more distinct and the ventricular electrograms less prominent, which makes the recordings more distinguishable (Fig. 17.15). However, standard ECG filters are 0.05 to 50 Hz, which are still not ideal for high-quality bipolar electrograms. The simplest solution is to perform the study in the intracardiac electrophysiology laboratory where the recording system includes variable filtering as needed and the pacing systems can provide the necessary output. When using a standard 12-lead ECG machine, a bipolar recording can be achieved by connecting two esophageal electrodes to

Figure 17.11. Diagrammatic illustration showing the recording and stimulation components of the transesophageal (TE) electrophysiologic technique. The recording mode (A) can be set up in a simple unipolar system (top) by connecting one esophageal electrode terminal to a surface ECG lead (e.g., V1) while recording one or two other simultaneous surface ECG leads (e.g., V2, V3). (See Figs. 17.12 and 17.15A for examples of unipolar recordings.) A bipolar recording system (bottom) can be used by adding a preamplifier. (See Fig. 17.15B for an example of a bipolar recording.) The stimulation mode (B) can be set up using either a bipolar or a quadripolar transesophageal electrode catheter. The bipolar electrode catheter permits only recording or stimulation, but not both simultaneously. An example of bipolar pacing using a bipolar electrode catheter is shown (top) with recording of the surface ECG during pacing. (See Fig. 17.13 for an example of ECG recording during pacing.) Simultaneous esophageal recording during pacing (bottom) can be accomplished in a unipolar or bipolar recording mode. (See Fig. 17.14 for an example of unipolar recording during pacing.) LA, left arm; LL, left leg; RA, right arm; RL, right leg.

the bipole of an ECG limb lead (e.g., right arm and left leg for lead II). Signal quality can be enhanced by the addition of a preamplifier between the catheter and the monitor/strip-chart recorder (Fig. 17.11A), but if it is not available, most studies can be performed adequately by adjusting the ECG high-pass filters to 0.5 or 1.0 Hz. A bipolar system is better than a unipolar system with regard to pacing-induced artifact, but the latter is not eliminated by a bipolar system because the high amplitudes and long pulse widths of bipolar transesophageal pacing present a problem in ECG recording and, therefore, measuring intervals. Benson et al. (42) have reported success using a prototype stimulus artifact suppressor that allowed for much-improved ECG recordings, but such a device rarely is used today.

The stimulator system requires capability for a long pulse width (≥ 10 m) and high current (10 to 25 mA) (42,43).

Several investigators have shown that pulse widths greater than the standard 2 m for intracardiac pacing are necessary to overcome high impedance and to penetrate the esophagus to reach the atrial (paraseptal) myocardium, particularly in non-infants. Although reports of pulse width duration for successful transesophageal atrial pacing have included low values of ≤ 2 m, atrial pacing is most consistent and reproducible at 6 to 10 m and current of 10 to 15 mA (28,29). Delivery of stimulus current >15 mA (at a constant pulse width of 10 m) is associated with patient discomfort (41,43). Moreover, lower stimulus current is needed at higher pulse width settings (e.g., 15 or 22 m). Therefore, for patients with high thresholds, discomfort can be minimized by increasing the pulse width, limiting the current threshold with a goal of <15 mA.

Transesophageal atrial pacing is most successful and best tolerated when performed at stimulator outputs $\geq 20\%$ above

Ventricular transesophageal pacing has been accomplished in adults by stimulating at high outputs currents ranging from 20 to 30 mA with a pulse width of 40 m and by using a specially designed flexible lead passed into the stomach (45,46). In a case report of ventricular transesophageal pacing in a 2,400-g premature infant with congenital AV block, high output also was required: 10-ms pulse width with 45-V amplitude (current was not specified) (47). Overall success rates of

Figure 17.14. Unipolar transesophageal simultaneous recordings (top) with surface leads V2 and V3 from a 3-year-old boy with incessant normal and wide QRS SVT (220-ms cycle length) showing simultaneous transesophageal pacing (interelectrode distance 24 mm) and recording (interelectrode distance 2 mm). Using a quadripolar electrode catheter, the esophageal recording (V, ventricular; A, atrial) during tachycardia was interrupted by 8 beats of atrial pacing (200-ms cycle length), which converted the tachycardia to several beats of sinus before wide QRS reciprocating AV reentrant SVT recurred. Note the wandering baseline of the unipolar esophageal recording before, during, and after pacing.

stable transesophageal ventricular pacing have ranged from 50% to 75% in adult patients. Data are not available from a pediatric series.

The pacing protocols for transesophageal pacing are limited, on a practical basis, to atrial pacing. As with the intracardiac pacing protocols, the specific protocols should be suited to the patient and the preprocedure diagnosis. In Table 17.2, a list of pacing protocols provides examples of several options used during transesophageal electrophysiologic studies.

Administration of Drugs

Sedative, provocative arrhythmic, and antiarrhythmic drugs are administered intravenously as individually indicated, similar to the intracardiac studies discussed earlier. The major differences relate to the practical application to primarily supraventricular arrhythmias in transesophageal studies, contrasted with both supraventricular and ventricular arrhythmias in intracardiac studies. The one caveat

Figure 17.15. Two transesophageal recordings (50 mm/s) in a 2,250-g newborn with atrial flutter (150-ms atrial cycle length) and 2:1 AV block showing a comparison of unipolar (A) and bipolar (B) recordings. Note that the prominent ventricular electrogram and the wandering baseline in the unipolar recording are eliminated in the bipolar recording. Therefore, the atrial electrogram is better delineated in the bipolar recording.

TABLE 17.2

Pacing Protocols for Transesophageal Electrophysiologic Study

1. Sinus node function
 - a. Sinus node recovery time
2. AV conduction
 - a. Continuous atrial decremental pacing
 - b. Premature atrial extrastimulation technique (during sinus and/or eight-beat drive of a-paced rhythm)
3. Atrial muscle refractory period
 - a. Premature atrial extrastimulation technique (during sinus and/or eight-beat drive of a-paced rhythm)
4. Induction of SVT
 - a. One or more of the following: Short bursts of a-pacing, continuous atrial decremental a-pacing, premature atrial extrastimulation technique (using one or more drive cycle lengths and one to three extrastimuli)
 - b. If unsuccessful, add provocative drug and repeat 4a
5. Determine SVT mechanism
 - a. Results of 4a, b
 - b. Record transesophageal electrogram, determine intervals
6. Determine drug efficacy/safety
 - a. Administer drug
 - b. For efficacy, repeat provocative a-pacing modes that induced pacing before drug
 - c. For safety, repeat steps 1–3
7. Terminate tachycardia
 - a. One or more of the following: Short bursts of a-pacing, continuous atrial decremental pacing, premature atrial extrastimulation technique (using one or more drive cycle lengths and one to three extrastimuli)
8. Risk stratification in asymptomatic or symptomatic WPW
 - a. Premature atrial extrastimulus technique to determine the antegrade effective refractory of the AP
 - b. Continuous atrial decremental pacing (or short bursts) to determine minimum cycle length for 1:1 conduction in the AP
 - c. Attempted induction of SVT as in steps 4a,b, and determine mechanism as in steps 5
 - d. Attempted induction of atrial fibrillation to determine the minimum preexcited RR interval during atrial fibrillation.

AV, atrioventricular; SVT, supraventricular tachycardia.

is ventricular tachycardias (VTs) that are reproducibly induced and terminated with atrial pacing like “Belhassen” tachycardia (48,49), where diagnostic and follow-up efficacy studies can be performed with transesophageal techniques.

Complications

Complications of transesophageal studies are infrequent and predominantly inconsequential (41,50,51). Mechanical or anatomic problems such as undetected obstructions or mucosal trauma or placement in a bronchus can arise during passage of the catheter through the nares and pharynx. These usually are recognized and are transient. Using lower stimulation outputs, no esophageal mucosal damage has been documented even after hours of continuous pacing if outputs are reasonably low. However, with

excessively high outputs esophageal damage can occur. Although technically not a true complication, transesophageal pacing in rare cases causes intolerable discomfort that is sufficient to disrupt completion of the study. Ventricular arrhythmias may be induced from inadvertent ventricular pacing or from rapidly conducting atrial-paced beats (51–53). This rare but serious problem of induced ventricular arrhythmias requires readily accessible DC cardioversion/defibrillation and resuscitative equipment.

OBJECTIVES OF DIAGNOSTIC ELECTROPHYSIOLOGIC STUDIES AND COMPARISON OF INTRACARDIAC AND TRANSESOPHAGEAL TECHNIQUES

One or more of the objectives listed in Table 17.3 are pertinent during electrophysiologic studies. The specific objectives performed relate to several factors, including arrhythmia diagnosis, underlying cardiac diagnoses, planned therapy, and which electrophysiologic technique (intracardiac or transesophageal) is used. The following discussion outlines the advantages and limitations of the two techniques relative to the objectives of the electrophysiologic study.

Ample studies of electrophysiologic results for both intracardiac and transesophageal techniques involving the objectives listed in Table 17.3 have been reported. The ability of the two techniques to accomplish the objectives of an electrophysiologic study encompasses multiple factors. It is important to realize the advantages and limitations of the two techniques. In this manner, when presented with an individual patient with a specific diagnostic or therapeutic problem, either the intracardiac or transesophageal technique (or both) can be chosen. Although the intracardiac technique may be superior in accomplishing virtually all of the clinical objectives, limitations in terms of cost, higher risk, and application in small infants may dominate in specific situations, making the transesophageal technique the best choice for the individual patient.

In Table 17.3, a comparison of the two techniques is graded (by opinion only) on a scale ranging from 0 (–), indicating no ability to accomplish the objective, to 4 (+ + + +), indicating an approximately perfect (or universal) ability to accomplish the objective. The inability to routinely pace the ventricle is the major limitation to the transesophageal technique. Therefore, when the objectives that involve ventricular pacing are analyzed, the transesophageal technique is inferior. Another major limitation of the transesophageal technique involves the fixed site of recording and stimulation, which limits the ability to effectively evaluate mechanisms of supraventricular arrhythmias, sinus node function (increased distance to sinus node), AV conduction, and site of AV block (inability to record HBE). The inability to reach the effective refractory period of the atrium is occasionally overcome by increasing the energy output. This is a potential limitation to the transesophageal technique, especially when attempting to fully evaluate patients with preexcitation when the AP refractory period is limited by reaching the atrial refractory period first.

Although the major advantages of the intracardiac technique involve its superiority in accomplishing specific objectives, the transesophageal technique is far superior in terms of cost, time commitment, and risk. Therefore, in many situations, limitations of the transesophageal technique are outweighed by its advantages. Also, it may be better to use one technique for a patient with a specific arrhythmia, but in another patient with an identical arrhythmia it may be better to use the other technique. In some patients, particularly in unique situations in which catheter access is a problem, the transesophageal technique is used during an intracardiac electrophysiologic procedure to provide additional and/or optional atrial recording/pacing site.

TABLE 17.3

Comparison of Intracardiac and Transesophageal Techniques to Accomplish Objectives of the Electrophysiologic Study

Objective	Intracardiac	Transesophageal
1. Determine cause of unexplained symptoms suggesting arrhythmia	+++	++
2. Terminate AV reentrant SVT, AV nodal SVT, or intra-atrial reentry/atrial flutter	++++	+++
3. Determine mechanism of ECG-documented SVT to define treatment options	+++	++
4. Assess efficacy/safety of antiarrhythmic drug therapy for SVT	++	++
5. Assess efficacy/safety of antiarrhythmic therapy for ventricular arrhythmia	++	—
6. Assess sinus node function	++	+

^aSVT only.

Finally, as noted above, the transesophageal study may be used before a catheter ablation procedure in the same setting to test arrhythmia inducibility in a patient with undiagnosed palpitations or for risk stratification in a patient with asymptomatic WPW. By understanding the limitations and advantages of the two techniques the cardiologist can optimally recommend the appropriate technique for the individual patient.

ELECTROPHYSIOLOGIC STUDIES—THERAPEUTIC CATHETERIZATION

In 1932, based on surface electrocardiographic data alone, Wolferth and Wood (54) correctly hypothesized that the structural abnormality underlying WPW syndrome (55) was an accessory AV connection or AP. However, it was not until Sealy et al. (56) surgically cured a patient with WPW syndrome and a right-sided AP that the anatomic basis of the disease proposed so long before was confirmed. This milestone also heralded the beginning of a prolonged debate concerning the optimal management of symptomatic and asymptomatic WPW syndrome: medical, surgical, or none. That debate has now changed from “which” to “when,” as ablation procedures have progressed from application of uncontrolled miniexplosions generated by high-energy defibrillator shocks delivered through the tip of a catheter, to precise localization of the atrial or ventricular AP insertion sites followed by temperature-controlled heating or freezing of a small volume of myocardium with RF (57) or cryoenergy (58). However, despite these changes, several questions regarding the early and late implications of catheter therapy in small children whose myocardial development is still underway remain unanswered (59,60).

This introduction to interventional electrophysiologic catheterization uses the treatment of AP-mediated tachyarrhythmias as a focal point for discussion. However, catheter-based therapy now has been applied to the cure or modification of most pediatric

arrhythmias, including AV node reentry tachycardia (61), ectopic atrial tachycardia (EAT), atrial reentry/flutter, congenital junctional ectopic tachycardia (JET), and some forms of VT (62).

THE DECISION TO ABLATE: SAFETY VERSUS EFFICACY

One overriding theme in the management of arrhythmias in children compared to adults is an emphasis on *safety* over *efficacy*. Although there are few cases at any age where safety is not an important concern, the relatively benign course of many arrhythmias in childhood, the potential disruption even therapies such as permanent pacing cause for a child, and the fact that parents are usually the decision making surrogate for the child, often lead to a different decision tree for children than in adults. Furthermore, for some situations and technologies, there are important differences (e.g., - the potential for coronary damage with RF energy application at the AV groove, the size of the patient and the heart).

Ablation in patients with WPW syndrome is an excellent example of how decision making may be age dependent (63). In this chapter, the term WPW is used to describe the condition of preexcitation on the surface ECG, with or without coexisting tachycardia. Due to a variety of concerns, even the most symptomatic infant with WPW and paroxysmal SVT only rarely is a candidate for ablation (64–66). Myocardial (60) and potentially severe coronary injury (67–70) are more likely with ablation in this age-group than in older patients. Furthermore, about 40% of APs in infants spontaneously stop functioning in the first year of life (71,72), and an additional third of patients are unlikely to have symptoms between infancy and early childhood (73). In children over the age of 4 years with symptomatic arrhythmias, the balance between risks and benefits clearly shifts toward ablation therapy, but

generally only if the ablation can be performed safely (63). In contrast to the situation in infants, even asymptomatic patients with WPW between the ages of about 8 and 18 years can be managed more aggressively than adults. Unlike asymptomatic adults over the age of 28 years, who are unlikely to ever have symptoms (74,75), the older child with a high-risk AP is exactly the type of patient who may present with sudden arrhythmic death as their initial symptom. This leads to the recommendation that such patients undergo risk stratification and those who are *high risk* be offered catheter ablation as a therapeutic option (76). Furthermore, the guidelines for sports participation in patients with WPW recommend risk stratification prior to approval for this age-group (77). Other age-dependent differences in management decisions are addressed when discussing individual arrhythmias below.

ENERGY SOURCES

Various energy sources have been used for ablation of myocardial tissue. Although many of the techniques rely on the generation of heat to destroy tissue, alternate mechanisms include chemically induced cell death, application of high current densities to disrupt intracellular membranes, and cooling to burst them.

Direct Current

In 1979, Vedel et al. (78) reported the first use of a DC shock through a catheter to produce complete AV block (inadvertently, in that case). His findings soon led to the use of DC catheter ablation for intentional production of complete heart block in a limited number of patients with drug-refractory supraventricular arrhythmias (79). Although the method was moderately successful in producing clinically effective AV block (~90% of 127 patients in one large series), complications were sometimes severe, including production of new arrhythmias, cardiac tamponade, and sudden death (80). With the possible exception of one series (81), similar results were obtained when DC ablation techniques were applied for the elimination of accessory AV connections or VT; moderate success was attained with infrequent but serious complications (82). Based on the results in adults, appropriate skepticism concerning the use of DC ablation in small hearts led to limited use of the technique in pediatric patients. Although success

was possible, a high incidence of complications has resulted in there being no current circumstances in which DC ablation is recommended for the treatment of arrhythmias in children (83,84). The so-called low-energy DC ablation technique (2 to 40 J) introduced in 1986 (85) was significantly safer than standard DC ablation, even within the CS, but its introduction was nearly simultaneous with the much more controllable RF techniques described below.

Radiofrequency

The theoretical advantages of controlled lesion formation using RF current to heat tissue combined with an existing neurosurgical experience using RF current (86) led Huang et al. (87) to attempt closed-chest ablation of the AV node with catheter-delivered RF energy. Their use of relatively low power (<50 W) appeared to provide adequate tissue heating to induce permanent AV block without significant complications, such as perforation or proarrhythmia, and with a lesion that was histologically well demarcated. The appeal of this technique was noted immediately by several investigators, such that by 1987, reports of the use of this technique in humans for both AV node and AP ablation were beginning to appear (88).

Since 1987, a number of studies, both in vitro and in vivo, in adult animals have confirmed that the cause of myocardial cell death with RFA is tissue heating to a temperature greater than approximately 50°C (57). Tissue heating to >90°C to 100°C is associated with tissue boiling, coagulum formation on the tip of the catheter, an increase in impedance, and a decrease in delivered current (89). Cell death appears to occur almost immediately at temperatures above 52°C, suggesting that cell death is the result of both protein denaturation and dehydration. The histologic changes have been described as coagulation necrosis (87). Haines and Watson (57) demonstrated that the lesion size grows exponentially with time, with a half-time of about 18 seconds. The temperature decreases hyperbolically with distance away from the electrode tip (inversely proportional to the radial distance) so that the lesion dimensions are directly proportional to the temperature measured at the tip-tissue interface. We have demonstrated similar findings for RF lesions made in immature myocardium (Fig. 17.16) (60). Thus, theoretically it is possible to accurately control lesion size by controlling the RF power output such that a particular preset temperature is achieved at the tip-tissue interface.

Current commercial systems supply RF energy at 500 KHz using a generator that can either supply unmodulated voltage/

Figure 17.16. Lesion volume as a function of the duration of RF application (A) and the electrode tip temperature (B). Volume increases exponentially as a function of lesion duration. For (A), the tip temperature was held constant at 80°C. The time constant (time required to reach 63% of the ultimate asymptotic lesion size of 79 mm³) was 22 seconds. Ninety percent of the maximum lesion was reached by 45 seconds. Lesion volume appeared to grow linearly as a function of electrode tip temperature. Previous data in adult animals had shown linear increase in width and depth with tip temperature.

power or control the temperature of the catheter tip through power modulation between 0 and 50, 60, or 100 W, depending on the manufacturer and catheter used (90). Energy is delivered in a unipolar fashion from the catheter tip to one or two large skin reference electrodes, positioned either on the patient's chest,

buttocks, or leg. During each RF application, voltage, power, current, impedance, and temperature are available and can be monitored continuously. Appropriate filters are available in most recording systems so that intracardiac electrograms and surface ECG leads can be monitored during RF delivery (Fig. 17.17).

50° C Test

70°C Application

Figure 17.17. A: Test application with radiofrequency (RF) generator set to 50°C. Maximum temperature achieved is 45°C. AP block occurs after 1.8 seconds and power is turned off after 3.1 seconds. AP conduction returns 3.6 seconds after turning off the power. B: After return of AP conduction, a full application is delivered with the RF generator set to 70°C. Peak temperature achieved is 56°C, and AP conduction block occurs at 1.5 seconds.

Control of catheter tip temperature during power application has not necessarily improved the success rate of ablation procedures, but has (a) almost completely eliminated overheating, impedance increase, and coagulum formation, (b) helped determine whether inadequate heating rather than incorrect catheter location is responsible for lack of success at a particular site, and (c) allowed low temperature heat mapping by intentionally producing low-temperature (45°C to 50°C) applications, which cause reversible electrical changes in the tissue (Fig. 17.17) (91).

As noted above, chronic lesions in adult dogs appear to be well demarcated histologically and are approximately the same size as the acute lesions (87). However, in 1994, we reported that chronic atrial and ventricular lesions produced in immature (~1-month-old) sheep may increase in size during the subsequent 6 to 8 months of normal development (60). This finding may have important implications for the use of RFA in very small children.

Cooled-Tip Radiofrequency

As noted, one of the limitations in creating larger RF lesions is that high temperatures at the tip-tissue interface lead to boiling, coagulum formation, and impedance increase, preventing further delivery of RF energy to the tissue. Over the past few years, it has become apparent that tip cooling can decrease the tip-tissue interface temperature, allowing the delivery of more RF power, pushing the peak temperature further into the tissue, and increasing lesion size by as much as a factor of two (92). Tip cooling can be accomplished passively with a more thermally massive tip (e.g., 8 to 10 mm in length, gold, etc.) (93) or by actively using a variety of methodologies (e.g., shower head, internal flow, porous metal, sheath flow) (92,94), achieving lesion widths and depths of 10 to 15 mm. Although this technique already has been critically useful for treatment of a number of arrhythmias, there are two important caveats. First, lesions can be too large, creating unintentional damage to structures, such as coronary arteries and second, cooling will reduce lesion size when maximum power is already being delivered with a noncooled ablation tip.

Microwave

In contrast to RF heating, which primarily is resistive, microwaves heat with a propagating magnetic field that have the potential to heat tissue at a distance from the origin of the field. In vitro studies with microwave antennas have shown that the volume of heating is probably somewhat larger than that seen with RF, but is more dependent than RF on antenna construction characteristics, electromagnetic frequency, and geometry of the antenna in relation to the tissue (95). Although there are no commercial microwave systems available now, microwave ablation some day still may have a bearing on the treatment of VT or atrial flutter, where larger lesions may be necessary, than for common forms of SVT, where RF and cryo techniques have been adequate.

Cryotherapy

Catheter-based cryotherapy was introduced into the clinical arena around the year 2000 for ablation of a variety of cardiac arrhythmias (96–101), but there are limited reports of its use in children (98,102,103). Cryoablation has several potential advantages over RFA, including (a) reversible cryomapping prior to the production of a permanent lesion (100,104,105), (b) adherence of the catheter tip to the endocardium upon freezing, (c) a well-defined edge of the cryolesion (104), (d) minimal effects on adjacent coronary arteries (106,107), and (e) a lower incidence of thrombus (108,109). The first four of these issues

are particularly relevant to small children because of the close proximity of a variety of critical cardiac structures to the ablation target. The most common reported major complication during RFA in pediatric patients is AV block (66,110,111), and there appears to be a higher potential for coronary artery injury in this patient group (68–70,112,113), even during slow pathway modification (70). Both of these effects appear to be much less likely or absent with cryoablation (114). However, despite previous belief that cryoenergy did not have the same potential for RF lesion growth in immature myocardium as reported for RF energy (60), a recent report from Khairy et al. (109) demonstrated that, in fact, cryoenergy produces nearly identical late lesion characteristics to RF energy in immature swine.

Cryotherapy is performed with a system that cools the tip of a catheter by expanding a liquid gas within the tip and removing heat from the surrounding blood and tissue. Systems allow for both ice *mapping* at a tip temperature of –25 to –40°C where the catheter adheres and nearby tissue loses electrical activity but few cells are killed and *ablation* at a tip temperature of < –65°C where a lesion will be formed. Once cells freeze, they expand and burst. After 4 minutes at the ablation temperature, a typical lesion size is 3 to 6 mm in diameter, smaller than those seen for RF. One of the contrasting features of cryoablation compared to RF is that there is a much larger zone of reversibility as the lesion expands because tissue cooling above the freezing point will lead to loss of electrical activation well prior to the loss of viability. This feature has dramatically enhanced the safety profile in clinical trials to date. In fact, despite frequent use of the technology for septal tachycardia substrates, there are no reports of AV block with cryoablation (96,98–101), even in children as small as 20 kg, in the presence of a His potential (Fig. 17.28)(103).

The primary disadvantage of cryoablation is that inherent in its high level of safety is a smaller lesion size than for RFA. For ablation of septal tachycardia substrates (AV node modification, anterior and posterior septal pathways), cryoablation success rates have been statistically similar to those for RF techniques (96,98–101). However, recurrence rates have sometimes been higher (115). Most operators are less aggressive with RF in septal areas and have had to be highly aggressive with cryotherapy to achieve success. Furthermore, with one exception in which 97% success was reported in a series of 24 pediatric patients with left-sided APs (116), even aggressive application of cryoenergy has not yielded similar success rates to RF for ablation of nonseptal APs. Although the data are limited in very small children and infants, anecdotal evidence suggests that cryoablation may be effective for all AP locations in these unique patient groups. Because of its acute safety profile, the use of cryoablation is most important for septal substrates, small children, and patients with abnormal anatomy where the precise location of the AV conduction system is not known.

Other

Any energy source that creates tissue heat has the potential to ablate myocardium in a similar manner to RF and microwave energy. Laser energy has been used to successfully ablate ventricular myocardium in both normal animals and humans with VT (117–119). The use of high-power ultrasound delivered through a catheter also has been reported as a means of heat ablation. One potential advantage might be the simultaneous use of diagnostic ultrasound to monitor lesion production (120). Finally, chemical ablation achieved by delivering a toxic agent such as alcohol into the coronary artery or vein supplying the myocardium responsible for an arrhythmia has been used in both animals and humans. However, technical problems with selective delivery will probably prevent this technique from ever reaching widespread use.

Summary—Energy Sources

Several energy types are available currently for use in catheter ablation procedures. However, currently, for procedures in children, cryotherapy and RF energy with or without tip cooling appear to have the best safety and efficacy profile. Both energy sources can reproducibly control lesion characteristics through assessment of tip temperature and application time. In general, RFA is more effective, but for the reasons discussed above, cryoablation is safer. At this time, the balance between which source is used for which procedure depends on the arrhythmia substrate, the location of the target, including the proximity of the AV node and coronary arteries, and the preference of the center and operator.

PROCEDURE—GENERAL

Preablation

Prior to the ablation procedure, standard electrophysiologic techniques should be used to identify the tachycardia mechanism, and, if appropriate, the location of the arrhythmia substrate. Differences from the standard study are related primarily to the actual mapping and ablation. Although not absolutely necessary, biplane fluoroscopy is very useful for precise 2-D localization of catheter tip positions. For most APs and AV node modifications, cameras are placed in the 30-degree RAO and 60-degree LAO positions, with 10- to 15-degree caudal projections (Fig. 17.4). In addition to camera angles, the development of deflectable tipped catheters with closely spaced electrode configurations, which are now available from a number of manufacturers, has greatly facilitated accurate mapping and ablation in all parts of the heart.

Three-Dimensional Electroanatomic Mapping

Over the past 10 years, a few novel methods have been introduced to simultaneously present 3-D, detailed electrical and anatomic information, facilitating mapping and reducing fluoroscopy exposure. One, termed “nonfluoroscopic,” uses a technology similar to a global positioning system to identify the precise catheter tip position and orientation (Fig. 17.18) (CARTO, Biosense—Webster, Baldwin Park, CA). Another, termed “noncontact,” uses the electrical signals in the blood pool of a cardiac chamber to derive an inverse solution for the signals on the endocardial surface (Fig. 17.5) (EnSite—St. Jude Medical, St. Paul, MN). Other systems provide simpler 3-D localizations of the catheter electrodes, using either impedance (NavX—St. Jude Medical, St. Paul, MN Fig. 17.6, and Loca-Lisa, Medtronic, Minneapolis, MN) or ultrasound localization (RPM, Cardiac Pathways), and can catalog catheter locations and timing signals during either mapping or ablation. Although location identification with impedance-based systems like NavX can be less accurate than the magnetic-based CARTO system, impedance-based systems do allow for location and timing data from any catheter, consequently providing faster collection of both geometry and timing data. Consequently, most available systems now have a feature for impedance-based catheter location. The location tracking and cataloging feature is an important component of all 3-D systems, enabling the operator to be aware of where critical cardiac structures are, where applications have been made and their outcome. Although all of these systems have their limitations, including high cost for the CARTO catheter and EnSite balloon catheter, it is clear that they contribute significantly to our understanding of arrhythmias and their mechanisms, and probably enhance success for complex cases (121–126),

reduce radiation exposure (20), and make completely non-fluoroscopic procedures possible.

PROCEDURE—SUBSTRATE SPECIFIC

Accessory Pathways

Mapping

Jackman et al. (127) and others have described important electrogram characteristics that help identify the precise location of antegradely and retrogradely conducting APs. Electrograms should be examined for the presence of probable AP potentials (Fig. 17.7) as well as the shortest AV time in preexcited sinus rhythm or atrial-paced rhythm and the shortest VA time during orthodromic reciprocating tachycardia or ventricular-paced rhythm (127). To help localize left freewall and left posteroseptal APs, a multielectrode catheter may be used in the CS (Figs. 17.2, 17.4, 17.19, and 17.20), but is probably not always necessary because it is the electrogram from the tip of the ablation catheter that ultimately determines the final ablation site. Typically, a deflectable tipped mapping/ablation catheter is used to localize right-sided APs on the tricuspid annulus either from the right femoral vein or the left subclavian vein. These techniques have been well described elsewhere (5,127). Some of the 3-D mapping techniques described above may be particularly useful for septal APs, to better understand the local anatomy, identify the location of critical structures, and identify prior ablation locations.

Ablation Catheter Manipulation—General

After initial localization, additional mapping and RFA are performed with introduction of a large-tipped (4 to 10 mm) steerable electrode catheter. These catheters are now available from a number of manufacturers in multiple sizes (5, 6, 7, and 8 Fr tips) and with a variety of deflecting curve options. For technical reasons, cryoablation catheters are not available in <7 Fr. The following standard approaches to AP ablation have been reported (5,127).

Left Freewall Pathways

Left freewall APs can be approached using a deflectable-tipped catheter advanced retrograde from the aorta into the left ventricle (5,127) or transseptal (5). For the retrograde approach, an attempt is made to place the catheter tip under and perpendicular to the mitral leaflet (Ao-LV) (Fig. 17.7) or through the mitral valve and above the mitral leaflet (LV-LV) (Fig. 17.19).

For the transseptal approach, the area of the foramen ovale is first probed with the mapping/ablation catheter for patency. If not patent, a standard transseptal puncture is performed using any of a variety of techniques and sheaths (see below). The mapping/ablation catheter then is placed through the transseptal sheath into the left atrium. Generally, the tip of the ablation catheter is maneuvered so that fluoroscopically it appears to be near the AV groove, confirming such location by the electrical recording from the distal pair of electrodes. Then the catheter tip is manipulated through deflection, rotation, and longitudinal movement to map the left AV groove. In many cases, catheter stabilization for mapping and ablation can be enhanced by deflecting the catheter and pulling it back into the sheath until only the four electrodes protrude, giving the appearance of a hockey stick (Fig. 17.20). Then the sheath and catheter are moved along their long axis as a single unit from septum to lateral freewall and the catheter torqued either clockwise (posterior groove) or counterclockwise (anterior groove) within the sheath. Access to left lateral pathways in larger patients sometimes requires exchange

Figure 17.18. Three-dimensional mapping using the CARTO, Biosense nonfluoroscopic system. Color scales go from red–orange being the earliest activation to blue–purple being the latest (see scale bar in images). Gray represents an area of low voltage determined to be scar tissue. Each white dot represents one point where the catheter was placed and activation times determined. The “face” at the top of each image shows the direction of the image (A) sinus rhythm—RAO projection (see face) of the right atrium (RA) in an adult patient with prior repair of a VSD as a child. As expected with sinus rhythm, activation spreads from the antero-lateral RA down toward the tricuspid valve. Activation lasts 122 m, from 79 m before to 43 m after the fiducial point (bar at upper left). The two images show the mapping catheter tip in two different locations acquiring mapping data—high lateral RA on the left and low septal RA just behind the tricuspid valve on the right. **A:** Tricuspid valve is now seen *en face*. Activation now proceeds from high anterior (red) down the septum, under the tricuspid valve and up the lateral RA wall. Activation now lasts 286 m from 149 m before to 137 milliseconds after the fiducial point (bar at left), encompassing the entire cardiac cycle. This could be considered “typical” atrial flutter circling the tricuspid valve, but in a clockwise direction. **B:** Atrial reentry/flutter—LAO caudal image (see face) of the RA. **C:** Atypical intra-atrial reentry tachycardia (IART). Straight left lateral view of the septal surface of the RA (see edge of face with eyes forward). This 27-year-old patient with tricuspid atresia began to have IART soon after an atrioventricular Fontan. After failing multiple medications and catheter ablation procedures, he underwent a right atriotomy and conversion to a lateral tunnel, but continued to have IART. After many subsequent years of failed medical therapy, he underwent mapping with the CARTO system demonstrating extensive atrial scarring, and a single IART circuit was identified encircling a large septal scar or ASD patch. Note counterclockwise procession from red to yellow to green to blue to purple in this left septal view. Ablation was successful with an actively cooled-tip system to block conduction in the inferior segment of the circuit (around the purple color). The patient has been asymptomatic since.

of the typical Mullins-type transseptal sheath for one of a variety of specialized sheaths that are now available (see below).

Most operators today prefer the transseptal approach for left freewall pathways in both adults and children, because it generally is more consistent, cannot damage the aortic valve or the left or right coronary artery orifices, and theoretically is less likely to damage ventricular myocardium. However, the overall results and complications from the transseptal and retrograde techniques are similar.

Right Freewall Pathways

Right posterior and right posterior paraseptal pathways almost always can be approached from the right femoral vein with a deflectable-tipped catheter placed above the tricuspid valve (IVC-RA). Right lateral and right anterior pathways can be approached either from the right femoral vein and IVC or from the right internal jugular vein and superior vena cava (SVC). For right lateral pathways, most operators find the

Figure 17.19. “Standard” retrograde approach from the aorta. The point of successful ablation is along the posterior AV groove at the sight of the large catheter tip. Note: overlapping of CS catheter in the LAO view, but catheter position well below the CS catheter in RAO view, indicating that the tip of the catheter is in the left ventricle.

use of a long vascular sheath (see below) very important to enhance catheter stability and improve access. Right anterior pathways also can be ablated on the ventricular side of the tricuspid leaflet (SVC-RV), using an approach from the SVC and placing the catheter tip through the tricuspid valve orifice (Fig. 17.2), as previously described (5).

Figure 17.20. Transseptal approach. The top two cine frames show a failed attempt to place the catheter retrograde through the mitral valve on top of the mitral annulus. The transseptal approach (bottom two frames) was successful with the catheter in position very close to, but slightly different from, the retrograde mitral approach. Note the hockey-stick appearance of the catheter tip (arrow) using the transseptal approach. A “Jackman” orthogonal catheter is in the CS, an octapolar catheter is at the HIS bundle, and a quadripolar catheter is at the right ventricular apex. The deflectable ablation catheter has a large tip. (From Saul JP, Hulse JE, De W, et al. Catheter ablation of accessory atrioventricular pathways in young patients: use of long vascular sheaths, the transseptal approach and a retrograde left posterior parallel approach. *J Am Coll Cardiol* 1993;21:571–583, with permission.)

Posterior Septal Pathways

For left-sided septal pathways, the retrograde aortic technique can be used with an attempt to deflect the catheter tip under the mitral valve near the aortic annulus. Alternatively, a transseptal approach can be used by extending the catheter all the way around the mitral annulus to the area of the septum. However, many of these pathways are intimately related to the CS (128–137) and only can be ablated within or around the CS (5,5). The CS and the region around the os can be approached from the right atrium, using the right femoral vein/IVC or the subclavian vein/SVC. (IVC-CS and SVC-CS). Regardless of approach, one must be aware of the small size and close proximity of the coronary arteries in this region. In fact, over the last few years there has been a realization that the coronary arteries in the posterior septal region may be at a higher than previously realized risk for collateral damage during application of RF energy in this region (69,70,112,113,138). Consequently, many operators now perform preablation coronary angiograms for any pathway near the posterior septum to evaluate the proximity of the ablation site to a small coronary artery. Pathway locations “near” a small coronary artery are either not ablated or are ablated using cryotherapy, for the reasons stated above in the description of cryotherapy, and below in the discussion of safety. This issue is particularly important for small children and infants, who have smaller coronary arteries and shorter distances from the ablation sites to the coronary artery.

Right Anterior Septal Pathways

These pathways are perhaps the most difficult to ablate safely, because of the close proximity to the AV conduction system. As with other anterior right-sided pathways, they can be approached from below via the IVC or above via the SVC. It is not uncommon that the best location for AP ablation also has a relatively large His potential on the ablation catheter, raising concern about unintended damage to the normal AV conduction system (Fig. 17.21). In fact, permanent complete AV block has been reported during RFA in as many as 10% of patients with right anterior septal pathways (111,139,140). Although rapid junctional acceleration during application of RF energy in such locations may predict impending permanent AV conduction system damage, AV block can be quite sudden in onset and permanent. A number of techniques can be used

Figure 17.21. Successful cryoablation of a right anterior septal AP. **A:** ECG at the initiation of cryomapping during tachycardia. His potential can be seen on the ablation catheter. **B:** Termination of tachycardia during cryomapping. SVT terminates with VA block just 0.6 seconds before reaching -25°C and 47.4 seconds from the initiation of cryomapping. **C:** ECG at the termination of cryoablation shows sinus rhythm and a His potential still on the ablation catheter. CS, coronary sinus.

to help avoid AV block. We have found that approaching the AV groove from above via the SVC allows for somewhat easier separation of the ablation location from the bundle by deflecting the catheter superiorly away from the His bundle. If the ablation catheter is seen lateral to the His catheter in the LAO caudal view, theoretically the His bundle should be at least a few millimeters from the ablation location. However, the most important advance we have found for these pathways is the use of cryoablation (97,103,141–144). Cryo systems allow for (a) observation of the effects without junctional acceleration when close to the normal AV conduction system, (b) reversibility during mapping at higher temperatures around -30°C , (c) catheter adhesion, and (d) the ability to electrically test AV conduction continuously during ablation (Fig. 17.21). Furthermore, even if cryoablation is unsuccessful due to early recurrence (119), often it is possible to identify a safe location for the application of RF energy to permanently ablate the pathway. As with coronary injury for posterior septal pathways, AV conduction system damage may be an even more important issue in children than in adults because of the close proximity of all cardiac structures in the smaller heart, and the larger impact of needing permanent AV pacing in a child. Thus, despite a higher recurrence rate than with RF, cryoablation is probably the therapy of first choice for septal pathways in the pediatric patient.

Use of Long Vascular Sheaths

The approach to left and right freewall pathways in particular can often be improved by use of one of a variety of long

sheaths, including 6, 7, and 8 Fr straight and specially designed sheaths. The presence of the sheath provides catheter stability, markedly improves torque transmission from the catheter handle to the tip of the catheter, and allows for coaxial steering of the catheter tip (5). These characteristics may be critical for the atrial approach on either the right or left side, even when a patent foramen ovale is present. The set of sheaths that has gained the widest appeal is designed to facilitate an approach to the left and right AV groove in which the catheter tip ends up parallel to the plane of the groove (Swartz Left SL1–4 and Right SR0–4, St. Jude Medical, St. Paul, MN). However, any sheath that helps deliver the catheter to the correct location will facilitate stability and enhance efficacy. These sheaths seem to be most helpful for right freewall pathways, but are designed for use in every right and left-sided location.

Ablation

Ablation can be performed in either sinus rhythm or orthodromic reciprocating tachycardia. However, if performed in tachycardia, the catheter is likely to move when the AP blocks and the tachycardia terminates. Thus, catheter stability during ablation of retrograde conduction can be improved by performing the ablation during right ventricular pacing and observing for loss of retrograde VA conduction during the ablation (Fig. 17.22).

When RF energy is being used and permanent ablation is desired, the initial catheter tip set point is usually 70°C . However, as noted above, a particular site can be tested for success by setting the desired temperature to 50°C and stopping RF application

Figure 17.22. Electrograms and RF outputs during an ablation. When RFA is performed during sinus rhythm (A), one can watch either the surface delta wave or the local AV interval. Note changes in both the surface ECG and the local electrogram (arrow) approximately 3 seconds after the application of RF energy. In (B), the RF application was performed during ventricular pacing for a concealed AP. RF outputs are not shown, but note how AV interval abruptly changes from 40 to 135 milliseconds, approximately 6 seconds after the application of RF energy. (From Saul JP, Hulse JE, De W, et al. Catheter ablation of accessory atrioventricular pathways in young patients: use of long vascular sheaths, the transeptal approach and a retrograde left posterior parallel approach. *J Am Coll Cardiol* 1993;21:571–583, with permission.)

at 5 to 10 seconds if success is not achieved, reducing myocardial damage to an absolute minimum (Fig. 17.17) (91). Based on the observation that permanent success is associated with early disappearance of AP conduction (127,145), lesions should be made for only 5 to 10 seconds unless the delta wave disappears, tachycardia terminates, or there is a noted change in VA conduction. If any of these three conditions are met, the temperature should be set at 70°C and the RF application continued for 30 to 60 seconds. Without temperature monitoring, the delivered power is likely to be too high or too low. Thus, with temperature monitoring,

the delivered power varies dramatically in an individual patient between individual applications, depending on catheter tip location and stability, both of which are affected by respiratory activity. Consequently, when general anesthesia is used, asking the anesthesiologist to hold respiration in either expiration or inspiration can markedly reduce catheter movement, improving the accuracy and effectiveness of the ablation application while reducing the possibility for catheter dislodgement.

When cryoablation is used, the system may be used in either the mapping or ablation mode, as described above. In either

case, as with RF energy, the earlier the effect the more likely the conduction block will be permanent. AP block prior to 15 seconds after a tip temperature of -25°C is reached is desirable. Once AP block is observed, cryoablation is performed at the lowest possible temperature (-70°C to -80°C) for 4 minutes. There is evidence that repeating the application for 4 minutes in the same location (so-called freeze-thaw-freeze) will significantly increase the lesion size and reduce the risk of recurrence, which may be higher with cryoablation than RFA (97,103,141). However, as experience has been gained with cryotherapy, initial and long-term results have improved (97,100,114,146–148).

Following creation of a successful lesion, patients usually are observed in the electrophysiology laboratory for 30 to 60 minutes, after which repeat electrophysiologic testing is performed, sometimes with and sometimes without an infusion of isoproterenol. A bolus of adenosine also may be used to unmask residual AP function by briefly reducing or eliminating AV node function and enhancing AP conduction (149). Most patients can be discharged on the day of the procedure or the morning after.

Results

Regardless of pathway location, the presence of multiple pathways, catheter approach, or patient age, initial success rates for elimination of APs can be as high as 98% (5,62,150,151), and typically range between 85% and 95% (5,62,90,150,151,152). The most reliable outcome data in children probably come from the Prospective Assessment after Pediatric Catheter Ablation (PAPCA)(151,153,154) in which 2,761 ablation patients from a wide variety of US centers were enrolled prospectively and 481 of them followed for a period of 2 years. Overall initial success rates for AP ablation were about 94%, with results varying significantly by locations (left freewall 98%, right freewall 90%, left septal 88%, right septal 89%). Fluoroscopy times can be long compared to other pediatric catheter procedures, but have generally come down over time (155,156). High variance in the difficulty of individual procedures, combined with the variability between investigators, probably attests to a large number of poorly defined factors that affect each procedure. However, the overall high success rates, sometimes requiring a second procedure, also indicate that these factors can be overcome.

From the 481 PAPCA patients followed prospectively, 12.3% of the 361 with an AP substrate had a recurrence within 12 months of the procedure (153). As with initial success, recurrence also varied by pathway location, varying from 4.8% for left freewall pathways to 24.6% for right septal pathways. Left septal had the lowest rate at 4.8% and right freewall were intermediate at 15.8%. Although these rates may be higher than in other reports from single centers or uncontrolled registries, they are the only data from a prospectively controlled trial in children and the subjects have the broadest center representation of any prospective ablation trial. Thus, these recurrence rates may be the most accurate representation of what can be expected in the average pediatric ablation center.

Permanent Form of Junctional Reciprocating Tachycardia

The permanent form of junctional reciprocating tachycardia (PJRT) is not strictly a pediatric disease. However, it occurs primarily in young patients, causing a nearly incessant tachycardia that frequently is refractory to medical therapy, and often leads to ventricular dysfunction (157). Despite the name, PJRT is caused by a concealed (retrograde only) AP with decremental conduction properties that classically has been

described to have a posterior septal location (157). The results of RFA studies that can confirm a precise AP location have demonstrated that (a) the majority ($>95\%$) of these pathways can be ablated and (b) their location may be in almost any position around the AV groove (Fig. 17.23) (158). The high safety and efficacy of RFA for PJRT, combined with the fact that pharmacologic therapy often is ineffective, suggest that catheter ablation probably is appropriate as first-line therapy for this syndrome, particularly if ventricular dysfunction is present (159).

As with any other AP, the method of ablation of PJRT pathways is dependent on location. Because many of the pathways are posteroseptal, ablation within the mouth or veins of the CS often is necessary. For such cases, coronary angiography should be performed prior to ablation. If a small coronary artery is within 2 to 3 mm of the expected ablation site, cryoablation should be strongly considered in place of RF energy. If cryotherapy is either unavailable or ineffective, RF energy application should be minimized by reducing catheter size, temperature setpoint, and maximum power and/or duration. High-energy RF application with active or passive cooled-tip technology should be avoided if possible within the CS or used with extreme caution.

Mapping virtually always should be performed during tachycardia. The VA interval during tachycardia generally is long with a long isoelectric segment between the ventricular and atrial signals, and an AP potential may be present in as many as 75% of cases (160). Recurrence rates are higher than for typical APs, and some patients may require more than one procedure for initial success (150,153,158,160–163). Of note, despite the proximity to the AV node, AV block has not been reported in the larger series of patients with PJRT who have undergone RFA (158,160–162).

Atrioventricular Node Modification

Dual AV nodal physiology is the substrate for AV node reentry tachycardia. Regardless of whether this physiology is the result of anatomic or functional dissociation of AV nodal conduction, it now seems clear that either the fast or slow AV nodal pathways can be modified to eliminate AV node reentry. Most early reports using either DC or RF energy to modify the AV node concentrated on eliminating conduction over the fast AV nodal pathway by delivering energy to an area just proximal to the His bundle, where a relatively large atrial and relatively small or absent His potential were recorded (164,165). When successful (80% to 95% of cases), this so-called fast pathway ablation usually results in significant prolongation of the AH and PR intervals, and, unfortunately, regardless of the energy form used, most investigators have inadvertently produced complete AV block in 2% to 10% of patients (164). Although these characteristics make the technique undesirable for most children and adolescents, a small number of successful fast pathway ablations was reported in pediatric patients without significant complications (61,62). However, since around 1994, almost all AV node modifications have been directed at the “slow pathway” by positioning the catheter inferior and posterior to the AV node (166).

The advantages of the slow pathway technique are that normal AV node function can be preserved in the fast pathway and the risk of complete AV block is lower than with a fast pathway ablation (62,150,166). Importantly, even this small risk of AV block virtually has been eliminated by the use of cryoenergy in place of RF energy for slow pathway ablation. In fact, no cases of unintended permanent AV block have been reported using cryoablation for the treatment of AV node reentry (97,100,102,103,141,167). It should be

Figure 17.23. Location of APs leading to PJRT. The schematic diagram reveals pathway locations as identified by successful RFA site. Circles represent pathways causing PJRT while the square represents a typical concealed pathway found as a second pathway in one patient. Note that four pathways were located outside of the typical posteroseptal location. (A–D) show representative angiograms of catheter-electrode positions in four locations. In **panel A**, the large tipped ablation catheter approaches from the IVC. Its final position is in the mouth of the CS, near the ostium of the middle coronary vein (posteroseptal pathway). In **panel B**, the ablation catheter approaches from the SVC and loops upon itself in the RAO view; together with the LAO view, the findings demonstrate a right lateral position. In **panel C**, the ablation tip is positioned via the SVC and overlies the distal HIS electrode, indicating a right anterior pathway. In **panel D**, the large tip catheter positioned in the CS was used for mapping only. A deflectable tipped catheter with a “dumb-bell” shaped electrode was used for ablation, and was positioned using a transseptal approach from the IVC to the posterior mitral annulus (left posterior pathway). (From Ticho BS, Saul JP, Hulse JE, et al. Variable location of accessory pathways associated with the permanent form of junctional reciprocating tachycardia and confirmation with radiofrequency ablation. *Am J Cardiol* 1992;70:1559–1564, with permission.)

noted that AV block is possible with cryoablation and there is at least one anecdotal case the author JPS has been told about, but none has been demonstrated in a publication. Initial recurrence rates in the early reports were somewhat higher with cryoablation than RFA of the slow pathway (97,100,102,103,141,167). However, more recent reports have found recurrence rates under 5%, similar to those with RF Energy (148,147,168).

When mapping the slow pathway, some investigators have found that the presence of a small electrical potential

from a presumably discrete slow pathway potential is a highly sensitive indicator of an appropriate catheter position (166), while others have found this slow pathway potential to have very poor specificity (169). Thus, many ablation techniques have been developed, including a purely anatomic approach to the inferior aspects of the AV node (169) and the use of slow junctional acceleration as an indicator of slow pathway node proximity. This latter observation is not useful for cryoablation because cooling of the slow pathway does not lead to junctional acceleration as

does heating. Consequently, the technique with cryoablation focuses more on elimination of slow pathway conduction with only transient changes to fast pathway conduction as procedural endpoints (102,103).

Using RF energy to modify the slow AV nodal pathway, the PAPCA study investigators reported that between 97% and 99% of AV node reentry tachycardia can be eliminated in children <17 years of age, but with a 2.1% incidence of AV block (151). Similar success rates can be obtained with cryoablation, but as noted above, most if not all of the AV block can be avoided (97,100,102,141). Cryoablation may be particularly important in smaller children, in whom the close proximity of both the fast and slow pathways to each other and the bundle of His provides a much higher theoretical risk of inadvertent AV conduction system damage. This potential for AV block with the subsequent need for long-term electronic pacing has led to a formal guideline recommendation that RFA for well-controlled SVT be delayed until age 5 years (63). However, this recommendation occurred before the availability of cryotherapy, a likely modifying factor when the guidelines are updated.

In addition to the risk of AV block, we reported coronary damage in a child undergoing slow pathway modification with RF energy for AV node reentry resistant to drug therapy (70). After transient ST changes were observed, selective coronary angiography showed a dominant right coronary artery giving off a posterior left ventricular branch artery that had an 80% stenosis (Fig. 17.24). The vessel course was within 2 to 3 mm of where the catheter tip was placed during the last RF application. Acute management was conservative, and after 2 days, repeat angiography demonstrated some improvement with an approximately 50% stenosis. Repeat selective right coronary angiography 2 months later revealed complete resolution of the narrowing (Fig. 17.24). Although this is the first case of coronary injury reported for AV node modification, coronary damage has been reported in many other posterior locations during AP ablation in humans and experiments in animals (67–69,139,170–172). Furthermore, this case highlights several important issues regarding the potential for coronary artery injury during RFA in children.

First, coronary artery injury may occur with slow pathway ablation for atrioventricular nodal reentry tachycardia (AVNRT). Second, acute coronary artery injury has the potential to be missed and is likely an underreported phenomenon. Third, infants and young children may be at particular risk. The inflammatory component of tissue injury caused

by RF energy has been shown to invade layers of the right coronary artery, leading to acute narrowing when RF energy is applied to the atrial side of the lateral tricuspid annulus in pigs (67). Furthermore, maturation of this injury can result in significant late coronary stenosis (112). Thus, with RF energy application, coronary stenosis may occur acutely or be delayed. Our patient's injury was nearly missed because ST segment changes did not occur until 100 seconds after the last RF application and resolved spontaneously within minutes despite a significant persistent stenosis of the involved artery. Other instances of coronary artery injury following RFA also have been nearly missed because of this delay (69,172,173). Alternatively, cryoenergy has been shown to have minimal to no effects on coronary arteries in animals (114,174).

To absolutely minimize the chance of coronary injury in children, the following should be considered for patients under 20 kg undergoing slow pathway modification for AVNRT: (a) cryotherapy is the preferred ablation methodology, (b) in all patients where RF energy is used, selective coronary angiography of the artery supplying the posterior septum should be performed prior to ablation, (c) if a small coronary artery is within 2 to 3 mm of the expected ablation location, RF energy should not be delivered, and (d) if any RF energy is delivered, acute follow-up angiography should be performed post ablation (173).

Ectopic Atrial Tachycardia

EAT is an uncommon form of chronic SVT primarily occurring in pediatric patients that often leads to cardiomyopathy and can be difficult to control medically (175). EAT in children typically is due to automaticity in a single non-sinus focus, which may occur almost anywhere in the left or right atria but tends to occur more frequently in the locations shown in Fig. 17.25. Left-sided foci near the pulmonary veins are more common in children (176–178), as opposed to right atrial foci in adults (179). Although EAT has been reported to resolve spontaneously in a few cases, the sometimes devastating effects of the arrhythmia on cardiac function, combined with the hypothesis that the arrhythmia arises from a single non-sinus atrial focus, and some reports of successful surgical excision of the focus (175) led to relatively early attempts at eliminating EAT with DC catheter ablation techniques (180). These attempts were promising, but the technique never gained wide acceptance because of

Figure 17.24. A: LAO projection of right coronary angiogram a few minutes after the ST segment changes in Figure 17.2 had spontaneously normalized. An approximately 80% stenosis (arrow) is seen in a posterior left ventricular branch off a dominant right coronary. The ablation catheter was moved away from the septum at the time of angiogram, but had been immediately adjacent to the stenosis during the RF application. B: Similar LAO projection of right coronary angiogram 2 months following ablation. Arrow marks area of prior stenosis, which is now resolved.

EAT Focus Location

Figure 17.25. Location of EAT foci in the first 25 patients ablated at Children's Hospital in whom detailed mapping was possible. Closed circles ($n = 23$) indicate sites of successful ablation, and open circles ($n = 2$) indicate foci that could not be eliminated, in one case because of a broad area of fibrous dysplasia that was resected at surgery, and another patient because of multiple atrial foci of which this was only one. LAA, left atrial appendage; RAA, right atrial appendage; PV, pulmonary vein; SVC, superior vena cava; IVC, inferior vena cava.

the risks of acute damage and the fears of chronic myocardial damage associated with the DC technique. In addition, there was considerable speculation that elimination of one EAT focus was inadequate due to the later appearance of others, particularly for right-sided foci (175).

Impressively, the use of RF catheter ablation for EAT has revolutionized its treatment. The first reported experience in a group of 12 patients who all presented with cardiomyopathy and drug-resistant EAT demonstrated that in all but one patient with diffuse atrial dysplasia, RF catheter ablation could successfully and safely eliminate the arrhythmia without long-term recurrence up to a median of approximately 2 years (176,178). Furthermore, the data demonstrated that the arrhythmia focus is anatomically very small, because tachycardia termination took place in a median of 2.0 seconds after application of RF energy (Fig. 17.26). These results now have been confirmed in larger series in which up to 96% of EAT foci in children have been successfully eliminated with RFA (62,146,151). Because of these high success rates using ablation and the morbidity of drug therapy, the question of drug therapy generally has been reduced to one of whether it should be attempted at all in patients with ventricular dysfunction, and if so, how long should one wait for reversion to sinus rhythm before proceeding to ablation.

Initial procedure failure and late recurrence tend to be associated with the presence of multiple foci or intermittent EAT during the procedure. Multiple foci portend poorly for long-term success (175), both because there is increased difficulty in differentiating the foci during mapping and more than one focus seems to be indicative of other foci emerging after the ablation procedure. Fortunately, in the pediatric population, most EAT is due to a single non-sinus focus.

Overall, EAT ablation seems to be extremely low risk. Pulmonary vein stenosis is the only unique complication and can occur when the EAT focus is near or within a pulmonary vein (Fig. 17.25). Clinically significant stenosis has not been reported for a pediatric case, but it was previously quite common in adults undergoing focal or narrow circumferential atrial fibrillation ablation procedures in similar locations (181–183). There is also a potential for damage to the sinus node or the right phrenic nerve for foci that occurs along the crista terminalis, but injury is less likely in a patient who has

Figure 17.26. Ectopic atrial tachycardia ablation. Note how ectopic P waves terminate immediately at the onset of application of RF energy. (From Walsh EP, Saul JP, Hulse JE, et al. Transcatheter ablation of ectopic atrial tachycardia in young patients using radiofrequency current. *Circulation* 1992;86:1138–3346, with permission.)

never had heart surgery because the phrenic nerve continuously slides over the epicardial surface of the heart. Most other EAT foci are not near vital structures, such as the AV node or a coronary artery (Fig. 17.25).

Atrial Flutter or Fibrillation in the Absence of Other Heart Disease

In the pediatric patient, atrial reentry tachycardias are relatively rare in the absence of either structural or functional heart disease. The term *lone atrial flutter* or *fibrillation* has been applied here, referring to the isolated nature of the arrhythmia findings. However, both of these tachyarrhythmias occasionally are observed in pediatric patients. There are two age ranges for presentation. Perhaps the most common is during third trimester fetal life when atrial flutter accounts for up to a third of fetal tachycardias (184), often lasting through delivery and leading to ventricular dysfunction. Neonatal atrial flutter almost universally resolves without recurrence if the baby can be managed successfully during fetal and early neonatal life (185). Consequently, ablation therapy for such infants should not be necessary and has never been reported.

A second presentation peak occurs during adolescence when both atrial flutter and fibrillation may present in the absence of any identifiable structural, hormonal, or chemical cause. Although initial management should be conservative, in contrast to the infants, the arrhythmia typically recurs multiple times in this age group despite medical therapy, creating a need for ablation therapy similar to the scenario in adults. The use of catheter ablation has been reported for both flutter and fibrillation in young patients. Success rates have been over 90% for the flutter subgroup in a relatively large series of patients in the Pediatric Ablation Registry (110). Interestingly, acute success has also been reported in seven of eight pediatric patients with paroxysmal atrial fibrillation who underwent ablation of either a single ectopic atrial focus or pulmonary vein electrical isolation (186). Furthermore, one of the cases

we included in a series of EAT ablations in 1992 (176) was a 12-year-old boy who presented with recurrent atrial fibrillation that was eliminated permanently after ablation of a single left pulmonary vein ectopic focus.

Specific technical details for ablation of either atrial flutter or fibrillation in the larger child are not particularly different from those in adults (187–189), so they are not reviewed here. However, the decision of when to ablate can be quite different, particularly for fibrillation. After conversion from a first episode of one of these arrhythmias, either no therapy or a drug to block the AV node response is adequate. After recurrences, the threshold for ablation of atrial flutter can be similar to that in adults. The use of ablation therapy for the rare cases of atrial fibrillation in pediatric patients also is appealing, but the high emphasis on safety over efficacy noted above for all children necessitates that a decision to use RFA in this age group be considered only after failure of multiple antiarrhythmic agents. Furthermore, the technique chosen should be the most conservative in terms of safety, since complications such as pulmonary vein stenosis and stroke may be devastating to a child.

Intraatrial Reentry Tachycardia in the Presence of Congenital Heart Disease

Commonly known as atrial flutter, intraatrial reentry tachycardia (IART) is uncommon in children with structurally and functionally normal hearts, but quite common after surgery for congenital heart disease. Although the prevalence is highest after either an atrial repair of transposition of the great arteries (Mustard or Senning technique) (190) or after the Fontan repair (191), IART may occur after any repair that includes an atrial scar (atrial septal defect, tetralogy of Fallot, etc.) (192). IART generally is easy to convert to sinus rhythm with DC cardioversion or atrial pacing via an esophageal lead, an intracardiac lead, or an implantable antitachycardia device (193). However, prevention is critically important in some patients because IART can be life-threatening (190,193) and increases the likelihood of atrial thrombus formation. Unfortunately, prevention of IART is much more difficult than cardioversion, with drugs of all classes being generally ineffective and, even worse, often unsafe (194). Consequently, RF catheter ablation to either prevent IART (195,196) or to eliminate AV conduction and institute ventricular rate-responsive pacing recently has gained prominence as a therapeutic option. IART in postoperative congenital heart patients may have multiple circuits in the same patient and be much more complex to ablate than “typical” atrial flutter, which generally is treated easily by electrically dividing the tricuspid annulus–IVC isthmus (195) (Fig. 17.27). Despite these complexities and a relatively high recurrence rate (125,197), acute success rates were initially reported at about 75%. However, since 2002, we and others have approached a rate of 95% (121,125,195,197,198). The use of 3-D mapping techniques probably is most important in this patient group (Figs. 17.5, 17.6, 17.18). Recurrence remains a problem, probably secondary to inadequate lesion formation, but technologies that produce larger lesions, such as the tip cooling techniques described above, will appear to improve even late outcome (121,125,126).

Junctional Ectopic Tachycardia

In the pediatric population, unlike in adults, JET occurs in two relatively distinct settings: postoperative and congenital (199,200). The electrophysiologic characteristics of both varieties are similar to those of EAT (200), suggesting they also are due to abnormal automaticity, in this case arising from either low in the AV node or high in the His-Purkinje system. However, direct intracellular recordings have not been obtained.

Figure 17.27. Sites of mapped exit points from zones of slow conduction at which ablation was attempted. In this schematic cartoon of the right atrium, *filled circles* represent 17 sites of successful termination of atrial reentry and *open circles* represent the presumed exit point of the circuit from the zone of slow conduction for five circuits not successfully ablated. A right atriotomy would normally be performed along the lateral reflected wall of the atrium in this view and may extend across the reflected opening to the base of the right atrial appendage; it is not possible to define with precision the sites of right atriotomy in individual cases. The crista terminalis would be expected to run along the line in which the right atrium has been opened in this view. SVC, superior vena cava; RAA, right atrial appendage; FO, fossa ovalis; CS, coronary sinus; TV, tricuspid valve; IVC, inferior vena cava. (Reprinted from Triedman JK, Saul JP, Weindling SN, et al. Radiofrequency ablation of intra-atrial reentrant tachycardia after surgical palliation of congenital heart disease American heart association. *Circulation* 1995;91:707–714, with permission.)

The postoperative and congenital forms of JET differ primarily in their duration and response to therapy (201–204). Postoperative JET typically is transient after ventricular septal defect repair, either alone or at the time of repair of more complex anomalies (205). It responds to cooling and a variety of antiarrhythmic agents (202–204). In contrast, congenital JET typically is chronic and incessant, but may resolve spontaneously over a period of years (200). Both JET types may result in severe hemodynamic compromise and appear to be exacerbated by both endogenous and exogenous adrenergic stimulation (200,204), and both arrhythmias seem to respond well to amiodarone (206).

The propensity for JET eventually to resolve spontaneously and the high theoretical risk of AV block from either catheter (83) or surgical (200) ablation of the JET focus in the AV junction suggest that JET initially may be best treated medically by minimizing adrenergic stimulation and beginning either intravenous or oral amiodarone (200,206,207), particularly in infants. However, anecdotal data from a few reports (207–213) and more recently a large series from a multicenter study (214) have demonstrated that with ablation, it is possible to eliminate JET while preserving AV conduction. The multicenter study from Collins et al. (214) reported ablation success in 83% of 17 patients undergoing RFA and 85% of

27 patients undergoing cryoablation, but few technical details were available in that report. Cryoablation was the preferred technology in recent years. Thus, when JET is resistant to medical therapy, persistent after a prolonged period of control, or producing intractable hemodynamic compromise, cryoablation probably should be attempted.

The specific details from the small number of reported cases of successful JET ablation provide few overarching recommendations to use when approaching these patients. Although in most cases, the region of interest has ended up in the anterior septum near the bundle of His, successful ablation in at least one case was reported in the posteroseptal region below the CS os, with the site identified using retrograde atrial activation as a guide (209). This region corresponds to the site used for slow pathway modification, and should be associated with a low incidence of permanent AV block. However, the data presented may be most consistent with frequent paroxysms of AV node reentry tachycardia triggered by junctional escape beats, and other investigators have not found mapping of earliest retrograde activation to be useful (211–213,215). Nonetheless, because this area generally is “safe,” initial attempts at ablation may be applied in the posterior septal region. If unsuccessful, mapping should focus on identifying the site of the earliest His potential during JET. Prior to ablation, the catheter should be moved very slightly posterior to that site, attempting to increase the atrial electrogram size and minimize the His activation from the distal ablation tip, similar to the methodology used in the past for fast pathway ablation. Most early reports of successful elimination of JET without causing AV block used this technique with brief, lower power applications of RF energy. However, there is probably a high risk of AV block in children using RF techniques, leading to the non-evidenced-based but probably appropriate switch to cryoenergy for ablation of JET. Figure 17.28 demonstrates the use of cryotherapy for ablation of JET in a 10-year-old with intermittently incessant tachycardia. Earliest His activation during tachycardia actually was found with retrograde mapping just under the aortic valve (Fig. 17.28). The intermittent nature of the JET in this case allowed for ablation during sinus rhythm. The high degree of safety of this methodology around the AV conduction system makes it ideal for both cryomapping and cryoablation, with successful elimination of the JET and preservation of the AV node, despite a catheter signal and location suggesting very close proximity to the His bundle. The outcome of cases like this (214) combined with the demonstrated reversibility of cryomapping applications suggests that cryotherapy should be the treatment of first choice for ablation of JET.

Ventricular Tachycardia

High success rates for both DC and RFA have been reported for two forms of VT in pediatric patients. In 1990, Morady et al. (215) first reported successful elimination of idiopathic

right-sided VT in 10 relatively young patients without structural heart disease using catheter-delivered DC energy. Other reports soon followed. In all of these series, pace mapping, as well as the site of earliest endocardial activation, were used as guides to the appropriate ablation site, but neither method was clearly superior. The youngest patient in any of these series was 18 years old, but a number of younger patients have since been reported (62,150,151,216–218). Both DC and RF energy also have been used to eliminate bundle branch reentry VT and idiopathic left VT by ablation of the right bundle branch or a left posterior Purkinje fiber (218,219). An entrainment technique that can identify sites most likely to ablate reentrant VT after myocardial infarction (220) has been used to successfully ablate reentrant VT in patients with tetralogy of Fallot and its variants (218,221–225).

COMPLICATIONS AND FOLLOW-UP

In children, acute major complications appear to occur in 1% to 2% of cases, and include complete AV block when ablating septal pathways (62,111,127,150,151), inadvertent coronary damage or coronary vein perforation (68–70,127,138), and vascular and embolic injury (61). Other minor complications have included Doppler-detectable increases in valvular regurgitation, minor vascular injury, and minor skin burns at the reference electrode skin site (5,62).

Follow-up studies have shown no evidence of new coronary abnormalities by traditional angiography at 1 to 6 months post ablation (5,127), and no significant increase in ventricular arrhythmias as late as 2 to 3 years. Importantly, however, acute coronary injury may not resolve (173), and animal studies have revealed coronary intimal thickening in arteries near the ablation site (69,112). Currently no data exist to assess the long-term effects of RF lesions on coronary function or arrhythmogenicity in developing infants and children.

The PAPCA study did not report any deaths in its 2,761 patients; however, in prior reports, death has been a rare complication of RFA procedures in children. Kugler et al. (62) reported a total of four procedure-related deaths in 4,135 children (0.097%) from 1991 to 1996, and Schaffer et al. (39) reported an incidence of 0.12% for patients with structurally normal hearts. The incidence was higher (0.89%) for patients with structural heart disease undergoing ablation.

SPECIAL CONSIDERATIONS FOR PEDIATRICS

Age (Infants)

There are three special considerations in infants that make their management different from the older patient when considering

Figure 17.28. Successful cryoablation at location with His potential in a patient with JET. (A) Identical His potentials are clearly seen from the ablation catheter (retrograde approach through the aortic valve) and from the His catheter (in a usual position) just prior to initiation of cryomapping. (B) Fluoroscopic images in the anteroposterior (AP) view shows the cryoablation catheter overlapping the image of the His position catheter. ABL, ablation; HBE, His bundle electrogram.

catheter ablation. First, the risk of a sustained reentrant primary atrial tachycardia, such as atrial fibrillation, is very close to zero in the small structurally normal heart, making the risk of sudden death in infants with WPW very low (71,226). Second, in approximately 40% of infants, AP function will spontaneously disappear by 1 year of age (71,72). Finally, the known risks of any catheterization, combined with the specific risks of catheter ablation in this age group (59,66,227–229), suggest that pharmacologic control should be aggressively pursued prior to ablation. This last issue deserves further discussion.

In humans, myocardial cell division probably occurs through approximately 6 months of age (230). Although this finding could potentially protect the myocardium from long-term complications secondary to early injury, the observation has been made that ventriculotomy scars produced in newborn puppies (231) and RFA lesions in immature lambs (60) appear to increase in size during subsequent development. Furthermore, as noted above, in neonatal swine, both RF and cryo lesions have been noted to increase in size with age (109). In addition, in contrast to mature ablation scars from adult animals, late lesions from the neonatal lambs and swine often were invasive and poorly demarcated histologically from the surrounding tissue (60,109). The potential clinical importance of these results is underscored by a reported sudden death 2 weeks after an AP ablation in a 5-week-old, 3.2 kg infant (5,59). An echocardiogram from the infant at the time of a brief resuscitation, and autopsy findings, revealed relatively large lesions extending into the left ventricle from the intended mitral groove ablation site. Another heightened risk in infants is coronary artery damage due to the potentially close proximity of the coronaries to the ablation catheter and the reduced capacity for protective cooling during RF application in any small coronary artery. Although most reports of coronary damage have been limited to the posterior septum or a non-dominant right coronary (67,69,70), complete occlusion of the left circumflex artery has been reported in a 5-week-old, 5.0 kg infant undergoing RFA of a left lateral AP (68), as well as in older patients (172,232).

Despite these disturbing cases, nonpharmacologic therapy will be necessary in a small subset of the infants with AP-mediated tachycardia (228,233). Until accurate methods are available to assess lesion size in real time, alternative methodologies should be used in all infants. Data on the effects of cryotherapy suggest that this form of energy may be much less harmful to coronary arteries, even when in very close contact (114,174,234), due to the differing effects of cold and heat on connective tissue and the vascular inflammatory response. Coronary artery flow also protects the vessel through local warming during cryotherapy, similar to how flow protects through local cooling during RF energy application. If technical or other considerations require the use of RF energy, considerable caution should be used. RF lesion size is related to catheter tip size, RF power, tip temperature, and lesion duration (235,236). Thus, the following technical modifications should be adopted: (a) deliver energy in as atrial a location as possible, (b) use a 5 Fr catheter tip, (d) use *low temperature mapping* (50°C to 55°C) to identify the correct location prior to higher-temperature RF application (91), (d) use a lower-temperature set point of 60°C for the ablation lesion, and (e) use shorter duration lesions (7 to 10 times the time to effect, with a maximum of 30 to 40 seconds). The future development of real-time ultrasonographic or other modality monitoring of lesion size may also help reduce the procedural risks (237).

Size

Patient size by itself does not appear to affect the success rate of catheter ablation, but has distinctly influenced the catheter

approach. Some have advocated using the standard retrograde approach to left-sided APs, but with two modifications: (a) a smaller catheter (5 or 6 Fr), and (b) fewer catheters, one for the ablation and one additional diagnostic catheter, both modifications designed to avoid vascular complications. Other researchers, including our own group (5), have worried about producing inadvertent ventricular lesions and have found that manipulation of the ablation catheter inside small ventricles is more difficult, leading to the use of the transeptal approach to all left-sided pathways, as described above. In fact, using the atrial approach, smaller patient size may actually make catheter manipulation easier, as discussed below.

Preexcitation Syndromes in Patients with Structural Congenital Heart Disease

Though not only a pediatric issue, the combination of structural heart disease and arrhythmias will clearly be encountered often by the pediatric electrophysiologist. In agreement with previous studies (238,239), a review of this issue in all database patients with congenital heart disease at the Children's Hospital in Boston found that preexcitation syndromes are statistically increased in patients with Ebstein malformation, congenitally corrected transposition of the great arteries (ccTGV), and hypertrophic myopathy (196). Of course, pre-excitation also occurs in other patients with congenital heart disease, but with an incidence not statistically higher than the general population.

Ebstein Malformation

The association of WPW with Ebstein disease and with the left-sided tricuspid valve in ccTGV probably has its basis in the embryology of tricuspid valve formation (240–242). The leaflets of the AV valves normally develop through a process of undermining, or delamination of the interior surface of the embryonic ventricular myocardium. Separation of the atrium from the ventricle occurs through completion of this process and encroachment of fibrous tissue from the AV sulcus. The mitral valve and the anterior leaflet of the tricuspid valve are fully delaminated early in development; however, the posterior and septal leaflets of the tricuspid valve are not even fully formed by 3 months gestation (242). Ebstein disease appears to occur when there is arrested development of tricuspid valve formation sometime between delamination of the anterior and the posterior leaflets. The high prevalence of preexcitation combined with anatomic findings of accessory connections in a number of selected cases of Ebstein malformation (241,243) suggests that the arrested valve development results in remnants of muscular or specialized tissue connections that cross the AV groove. In fact, multiple pathways are common in these patients, often with a combination of a posteroseptal pathway and one or more additional freewall pathways.

The electrophysiology of the APs in patients with congenital heart disease is not particularly unique. Bidirectional, antegrade only and retrograde only pathways have been reported. Furthermore, these patients have the same range of tachyarrhythmias found in patients with structurally normal hearts: orthodromic and antidromic AV reciprocating tachycardia and other SVTs (AVNRT, atrial flutter/fib, and so on) with bystander participation of an antegradely conducting AP. However, the physiologic and clinical implications of the tachycardia may be markedly different in patients with congenital heart disease.

Abnormal hemodynamics, increased incidence of isolated atrial and ventricular ectopy, sometimes poor tolerance of antiarrhythmic therapy, and the need for surgical repair that

accompanies congenital heart disease all contribute to an increased need for aggressive arrhythmia management in this patient population. However, abnormal anatomy and atypical conduction systems may also enhance the difficulty and risks of either surgical or catheter ablation. Though difficult, RF catheter ablation results have been good enough to recommend the procedure in: (a) all patients requiring subsequent surgical repair to avoid postoperative arrhythmias as a complication and (b) most symptomatic patients over 1 year of age with significant structural lesions. A review of the reported cases of RFA in patients with congenital heart disease shows that most of the patients have Ebstein malformation (127,152,244–246). However, a significant portion has more complex anatomy with AV valve discordance and, often, heterotaxy. Multiple pathways are extremely common in this group, occurring between 30% and 80% of patients (127,243–245,247), compared to 5% to 10% in patients without congenital heart disease (127,152,248–250). It is interesting to note that similar to the patients with Ebstein malformation, patients with AV discordance had all of their APs associated with the tricuspid valve regardless of atrial situs, AV relationship, or valve function. This finding is in contrast to the more random location of APs reported for patients without congenital heart disease (127,152,248–253). Hypertrophic cardiomyopathy is the exception where pathways are more likely to be on the normal left-sided mitral valve.

Some aspects of the procedure in patients with Ebstein malformation are of special note. First, differentiation of atrial and ventricular signals and precise localization of the AV groove can be difficult, leading to a lack of specificity for what appear to be excellent signals in predicting a successful ablation site. In fact, very early ventricular activations, which might be termed “pseudo” AP potentials can often be seen near the AV groove (Fig. 17.29). This issue is particularly important for older patients who have large hearts with poorly defined AV grooves. The true AV groove is best identified by the right coronary artery. Use of a right coronary electrode wire can be considered (248,254), but may be difficult due to a diminutive right coronary artery, and may need to be in place for long periods when multiple pathways are present. A safer recommended alternative is continual display of the relevant coronary angiogram using a real-time biplane image storage and display system. As with any AP, searching for balanced atrial and ventricular electrograms during mapping is important. Despite these maneuvers, it may still be very difficult to define the AV groove in these patients, requiring more test applications of the ablation modality to identify the correct location. Catheter stabilization for freewall pathways in the largest hearts is difficult and is not sufficiently improved through the use of a long sheath or a variety of approaches (5) (see prior section). One observation that is difficult to prove statistically is that the smaller chamber size in smaller patients with structural heart disease is a technical asset in catheter ablation. In one series (244), a total of seven procedures lasting an average of 4.1 hours were required to ablate seven of nine accessory connections in six patients under 40 kg, whereas seven procedures lasting an average of 6.5 hours were used to ablate only three of seven connections in four patients who weighed over 40 kg.

As expected, it appears to be impossible to approach the ventricular side of the tricuspid valve in patients with Ebstein malformation. No specific reports have noted the use of *nonstandard* ablation technologies for the patient with Ebstein malformation, but a few observations can be made. Coronary damage has been reported on multiple occasions in patients with Ebstein anomaly (69), probably due to the thin RV wall and often diminutive right coronary artery. Consequently, despite the tendency to use higher-power active or passive cooling ablation systems for difficult cases, such technologies

should only be employed when an adequate distance between the catheter tip and the artery has been documented. The definition of “adequate” depends on the size of the nearby coronary artery—the larger the size, the safer the ablation. Furthermore, strong consideration should be given to the use of cryotherapy, at least as a mapping tool. Safety will be enhanced and the adhesion of the catheter may be particularly useful in the larger patients.

When multiple pathways are present, persistence may be the electrophysiologist’s best weapon for successful ablation. In general, 80% to 90% of patients can be rendered arrhythmia free by the procedure, with relatively infrequent major complications, such as permanent AV block (127,150,244,245). However, recurrence rates have been reported as high as 40%, particularly when multiple pathways are present (127,150,244,245).

FIGURE 17.29. Electrograms near the AP with Ebstein malformation. Electrograms A through F were recorded with the distal pair of an ablating catheter very near the point of successful ablation shown in F. Note early ventricular activation in parts A through D, despite lack of success. Electrograms in parts D and E were not significantly different, but part E had transient success. F, the point of permanent success, probably has the earliest activation; however, the differences are much clearer in retrospect. The dark vertical line marks the point of earliest surface QRS activation for all electrograms. G shows the position of the atrial and HIS electrograms. Pathway location was posterior septal.

Figure 17.30. A: A cartoon demonstrating the locations of the mitral valve (MV), tricuspid valve (TV), the His bundle, and APs in three patients with preexcitation syndromes and atrioventricular discordance. Patient 1 corresponds with parts (A) and (B). The angiogram in the anteroposterior projection (B) illustrates the importance of defining the anatomy of the AV valves. The decapolar catheter (bottom white arrow in B) was advanced from the left-sided IVC across the mitral valve and positioned with the second pair of electrodes at the His bundle. The mapping catheter (black arrow in A, upper white arrow in B) was advanced from the IVC across the atrial septum to the right-sided (anatomic) left atrium and positioned at the location of the AP, which in this case was at the superior and anterior portion of the left-sided tricuspid valve. The unmarked catheter is an atrial pacing catheter in the left-sided right atrium. DORV, double outlet right ventricle; PAPVC, partial anomalous pulmonary venous connection; TGA, transposition of the great arteries.

Corrected Transposition

Ablation procedures in patients with AV discordance (S,L,L or I,D,D) require special considerations. First, detailed echocardiography and angiography are instrumental in defining the complex anatomy of the atria, the AV ring, and the CS, so that the cameras and catheters can be positioned appropriately (Fig. 17.30). Second, careful attention must be given to locating the normal conduction system. Virtually, all patients with AV discordance have had their AP associated with the tricuspid valve, while the His bundle has been associated more closely with the mitral valve. As predicted by Ho and Anderson (255), the normal conduction axis often is located at an anterior position along the AV groove. Once the “normal” and abnormal conduction fibers are located, electrophysiologic study and RFA of the APs can proceed with less risk

of damage to the normal conduction system. Mapping and ablation requires a detailed knowledge of the anatomy and often innovative approaches. For instance, for cases of atrial inversion (*right atrium* on the left, and vice versa) with AV discordance (I,D,D), an atrial approach to the right-sided tricuspid valve may require a *reverse* transeptal procedure from the left-sided IVC and right atrium to the right-sided left atrium. If present, the CS in such cases will also be reversed. AVNRT may also be present in these patients, requiring identification of the slow pathway of an AV node that is typically along the anterior mitral annulus. Clearly, the need for a detailed understanding of the anatomy in these cases cannot be overemphasized. Ablation technologies similar to those recommended above for Ebstein patients, including cryoablation as the preferred energy source, are applicable to AV discordance patients as well.

Double Atrioventricular Nodes

In hearts with discordant AV connections, the AV node typically is situated superior and anterior in the atrial wall near the antero-lateral quadrant of the mitral valve (240,255). A second AV node that often is present more inferiorly in the normal area of the triangle of Koch can also link to the ventricular conduction fibers posteriorly, usually inferior to a ventricular septal defect. If the posterior and anterior ventricular bundle branches link together, a conduction sling, sometimes referred to as a “Monckeberg sling,” is formed (Fig. 17.31) (240,256,257). These anatomic findings provide the substrate for a host of different modes of ventricular excitation or preexcitation and AV reciprocating tachycardias. However, prior to our reports, there had been no electrophysiologic documentation of this phenomenon (258,259).

In 2001, we reported seven such cases, all of whom had AV discordance (2-S,L,L and 1-I,D,D) and characteristics consistent with the diagnosis of two separate AV nodes (twin or double) (258). Five of the seven also had malaligned AV septal defects. The electrophysiologic findings included: (a) the existence of two discrete nonpreexcited QRS morphologies, each with an associated His-bundle electrogram and normal HV interval; (b) decremental as well as adenosine-sensitive anterograde and retrograde conduction; and (c) inducible AV reciprocating tachycardia with anterograde conduction over one AV node and retrograde conduction over the alternate AV node. Ventricular premature beats placed into tachycardia when the His was refractory could preexcite the atrium, indicating that the tachycardia involved two AV connections. In all cases, applications of RF energy at the site of the bidirectional pathway resulted in transient *junctional* acceleration with an identical QRS morphology to that generated by anterograde conduction over the targeted AV node and modified or eliminated antegrade and retrograde conduction at that site. Although there is a possibility that one or the other of these pathways was a *Mahaim-type* AV fiber, their locations and the presence of near-normal HV intervals, retrograde conduction, *orthodromic* tachycardia, and *junctional-type* acceleration during RFA all favor a second AV node. The precise etiology may make little difference for the management of such patients, but the phenomenon is important to be aware of to avoid damage to the more robust of the two conduction systems during ablation procedures performed prior to surgery in these patients with complex anatomy.

Clearly, an extensive understanding of the anatomy and electrophysiology should be obtained in such patients before proceeding to mapping and ablation. Furthermore, the lack of clarity in defining the anatomy of AV conduction in these patients suggests that ablation should first be undertaken using cryotherapy, proceeding to RF energy only if unsuccessful or after a recurrence. The one caveat to this recommendation is that low-power RF application may be helpful in identifying the location of the anterior and posterior AV nodes through their acceleration response when heated.

Preexcitation and Congenital Heart Disease: Summary

A few recommendations concerning catheter ablation in patients with congenital defects can be made: (a) an attempt should be made to carefully identify the location of the normal AV conducting system, particularly in patients with AV discordance, (b) the anatomic tricuspid valve is the most likely location for accessory connections, (c) smaller patient size may be an asset, (d) an atrial approach probably should be attempted first for connections around the tricuspid annulus (right or left sided), (e) the true AV groove should be well identified, using atrial and ventricular electrogram balance, a coronary angiogram, or if feasible and available, a coronary

Figure 17.31. A: Diagram of the base of the heart and the AV conduction system in congenitally corrected transposition of the great arteries (corrected) as seen from above. Note the bicommissural mitral valve on the right and the tricommissural tricuspid valve on the left. The AV node may either lie posteriorly (Post. Node) in the septum in a somewhat normal location, anteriorly on the right-sided mitral valve (Ant. Bundle) or in both places (Anderson RH, Arnold R, Wilkinson JL. The conducting system in congenitally corrected transposition. *Lancet* 1973;1:1286–1288, with permission, Ref. 260). B: Diagram of the conduction system from a patient with corrected transposition in a criss-cross heart, with AV valve anatomy similar to that shown in (A). Note the dual conduction system with both the posterior and anterior AV nodes penetrating into the ventricles and near connection of the conduction systems within the ventricle.

mapping wire in larger patients, and (f) whenever possible, cryoenergy should be considered as the ablation technology to minimize the risk to the AV conduction system and adjacent small coronary arteries. With these caveats in mind, it appears that despite the difficulties of unusual anatomical landmarks and abnormally positioned conduction systems, most APs in patients with structural congenital heart disease can be ablated safely and effectively.

SUMMARY

Children are usually smaller than adults, but in general ablation techniques used in adults should not simply be miniaturized to fit the size of the pediatric patient. Multiple factors, including the distribution of arrhythmia mechanisms, ongoing myocardial development, potentially increased risk of vascular injury and AV node damage, as well as the effects of smaller cardiac size should all influence the ablation technique. An overriding theme in the child should be that safety takes precedence over efficacy. Thus, variations of technique should include the decision to ablate, the energy source and its delivery, the catheter approach to the heart and the AV ring, and the follow-up. For instance, because of its strong safety profile and despite lower efficacy, the use of cryotherapy may be even better suited to ablation in children than in adults. Attention to these factors probably is most important in infants. In addition, the pediatric patient is more likely to have the simultaneous presence of structural congenital heart disease, which in itself has a variety of implications for the decision to ablate and the procedure technique. Alternatively, there are numerous similarities between adult and pediatric patients. Specifically, regardless of age, it seems clear that a variety of techniques and approaches is necessary to successfully ablate APs in all locations around the AV groove.

Disorders of Cardiac Rhythm and Conduction

Bryan C. Cannon ■ Christopher S. Snyder

Arrhythmias are common in the general pediatric population and frequently are an important clinical problem in patients with structural congenital heart disease. Arrhythmias have a broad spectrum of clinical presentations, ranging from no symptoms to sudden death. There is a wide variety of causes of arrhythmias and an even broader range of treatments. On the most basic level, arrhythmias can be divided into bradyarrhythmias and tachyarrhythmias.

SINUS NODE

The sinoatrial node is an extensive, subepicardial structure located on the crista terminalis of the right atrium between the inferior and superior vena cavae (1). The blood supply to the sinus node has three major variants, with the right coronary artery supplying it 60% of the time, left circumflex coronary artery 36%, and the remainder by both coronary arteries (2). The main function of the sinus node is electrical; therefore, it is dependent on ion channels. These cells have unique properties and exhibit a slow, spontaneous phase 4 depolarization known as the pacemaker potential that is affected by circulating catecholamines (3). The sinus node also has a very strong sympathetic and parasympathetic innervation through cardiac ganglionic plexi that directly affect the rate of depolarization. Increased sympathetic tone increases depolarization, while increased parasympathetic tone reduces depolarization. Disorders in any of these areas can result in abnormal sinus function resulting in bradyarrhythmias or tachyarrhythmias.

ANATOMY OF THE ATRIOVENTRICULAR NODE

The atrioventricular (AV) node is the electrical structure that connects the atrium to the ventricles. It is a complex structure made up of different structures that are based on variable cellular morphology and function. It generally is located at the base of the interatrial septum within the triangle of Koch. As with the sinus node, it has a very rich autonomic innervation with both sympathetic and parasympathetic neurons (4). Its main function is to allow delayed impulse transmission from the atrium to the ventricle. This delay ensures that the atria have a chance to contract before the ventricles are stimulated. When the sinus node fails, the AV node has automaticity and can function as an escape pacemaker.

The AV junction consists of transitional cells, specialized nodal cells (AV node), and the penetrating AV bundle (bundle of His) (Fig 18.1). The first part of the AV node is the transitional cells. These cells tend to be laid into tracts (i.e., the fast and slow pathways) that lead directly from the atrial myocardium into AV node proper (5). As the cells exit the compact

bundle, they begin to organize into larger individual bundles separated by fibrous tissue. As the lower cells progress even more distally, they form the penetrating AV bundle. The penetrating bundle is engulfed by the central fibrous body (CFB) and also is referred to as the bundle of His. Conduction exits the bundle of His into the ventricles via the left and right bundle branch and the Purkinje fibers. Abnormalities affecting this complex series of fibers at any level can result in AV block or tachyarrhythmias.

TACHYCARDIA

An abnormal mechanism of tachycardia, or tachyarrhythmia, results from an area other than the sinus node elevating the heart rate above the sinus rate or alternatively from an intrinsically abnormal sinus node. Tachyarrhythmias arise as a result of abnormal impulse initiation or conduction and may be classified in several different ways. One way to classify tachyarrhythmias is based on their mechanism of initiation and propagation. There are three basic mechanisms by which tachyarrhythmias start: reentry, abnormal automaticity, and triggered activity. It is important to understand these mechanisms because the clinical presentation and features of the tachycardia depend on their underlying mechanism.

Reentry is the most common form of tachyarrhythmia and is responsible for most supraventricular and many ventricular tachycardias (VTs). For reentry to occur, two distinct conducting pathways must be linked around an area of nonconducting tissue. One limb of the circuit must display slow conduction while the other limb has a long refractory period (Fig. 18.2). This type of arrhythmia can be terminated if one or both limbs of the tachycardia are disrupted. They usually have a rapid onset and offset (usually in a single beat) and may present with rates above 300 beats per minute. Examples of reentrant tachycardias are AV node reentry tachycardia, accessory pathway-mediated tachycardia, and atrial flutter.

Automaticity is the ability of a cell to depolarize spontaneously. With abnormal automaticity, there is either abnormally fast activation of cells that exhibit automatic function or development of spontaneous depolarization in cells that typically do not possess automaticity. Abnormal automaticity often has a metabolic cause (electrolyte disturbances, thyrotoxicosis, hypoxia, ischemia, fever, etc.). It can occur in otherwise normal children but also frequently is seen in acutely ill children and often exacerbated by intravenous sympathomimetics. The arrhythmias caused by abnormal automaticity show behavior similar to sinus rhythm in that they speed up and slow down according to metabolic changes and are generally refractory to direct current cardioversion. Examples of enhanced automaticity include atrial ectopic tachycardia (AET), junctional ectopic tachycardia (JET), and some forms of VT.

Figure 18.1. AV node anatomy. This diagram illustrates the location of the AV node within the triangle of Koch. One can follow the propagation of a sinus beat down the fast and slow pathways, through the compact AV node, located within the CFB, to its exit into the His bundle. CS, coronary sinus; IAS, intra-atrial septum; FO, foramen ovale; IVC, inferior vena cava; TrV, tricuspid valve; CFB, central fibrous body.

Figure 18.2. Mechanism of reentry.

A: Reentry involves two interconnected limbs of tissue that conduct electrical impulses with an area between the two with no electrical conduction. One limb has fast conduction with a long refractory period. The other limb has slower conduction but a shorter refractory period. **B:** If a premature impulse occurs, it may block in the rapidly conducting limb and conduct down the slow limb only. **C:** When the impulse reaches the connection between the two limbs, the faster conducting limb is no longer refractory and able to conduct a retrograde impulse. **D:** This retrograde impulse then activates the slowly conducting tissue setting up the reentrant circuit.

TABLE 18.1

Approximate Normal Resting Heart Rates in the Pediatric Population by Age

Age	Resting Heart Rate (bpm)
Birth-1 wk	90–160
1 wk–1 yr	100–170
1–2 y	80–150
3–7 y	70–135
7–10 y	65–130
11–15 y	60–120

The third and most rare mechanism of arrhythmogenesis is triggered activity, which has features of both automaticity and reentry. This is the result of an after-depolarization, which is an abrupt change in the membrane potential during the action potential (early after-depolarization) or following full repolarization (delayed after-depolarization). This may serve as a stimulus for an ensuing action potential, leading to a sustained arrhythmia. These after-depolarizations are a feature of many drug-induced arrhythmias (such as digitalis toxicity), and triggered activity is associated with the initiation of ventricular arrhythmias in long QT syndrome (6).

Clinical Presentation

Normal heart rates in pediatric patients are age dependent (Table 18.1). One must realize that these are normal *resting* heart rates. The challenge is actually obtaining an accurate resting heart rate. Palpation of a child's pulse or obtaining an ECG can lead to fear and/or anxiety, thereby increasing heart rate through significant sympathetic input. The maximum sinus heart rate that one can achieve is typically 220 beats per minute minus the patient's age. Although heart rates above 220 beats per minute rarely can be sinus in origin, heart rates in this range should warrant evaluation for an abnormal mechanism of tachycardia. Initiation and termination of tachycardia with a single beat also should raise suspicion for an abnormal mechanism of tachycardia. Syncope is a relatively uncommon presentation of tachycardia in the absence of other symptoms suggesting an arrhythmia or underlying channelopathy.

Evaluation

The most important aspect for diagnosis of tachyarrhythmias is the electrocardiogram (ECG). Documentation of the electrocardiographic rhythm during times of symptoms or tachycardia is the cornerstone for differentiation between sinus tachycardia and abnormal mechanisms of tachycardia. Ideally, this is performed as a 12-lead rhythm strip but may be done in any manner capable of recording and documenting the ECG. As arrhythmias may stop suddenly without warning, immediate documentation should be one of the first steps in managing a patient with a tachyarrhythmia following assessment for hemodynamic stability. The most helpful ECG for a specific diagnosis of a tachyarrhythmia is during times of "wobble": when a tachycardia, starts, stops, or changes. Therefore, a continuous ECG strip should be performed *during* the time of any intervention to terminate tachycardia, not just before and after.

At times, it can be difficult to diagnose the exact nature of a tachycardia based on an ECG or rhythm strip alone. In these cases, it may be necessary to use other diagnostic tools to characterize the tachycardia. Vagal maneuvers such as Valsalva or the dive reflex may be used to alter the tachycardia or in some instances terminate it. The dive reflex is initiated by placing a bag of ice over the entire face (including the nose and mouth) for a period of 10 to 15 seconds or submersing the entire face in an ice water mixture. Although this is a strong vagal stimulus, it may be alarming to parents, and care should be taken in small patients to avoid superficial damage to the skin from the ice. Other vagal maneuvers such as ocular stimulation, carotid massage, gagging, and rectal stimulation are best avoided in the pediatric setting.

Postoperatively, atrial temporary pacing wires can be used to obtain a pure atrial signal when it is difficult to determine the relationship of the P wave to the QRS during tachycardia. The two atrial pacing wires are connected to the white (right arm) and black (left arm) leads. This gives a distinct deflection representing atrial activity in lead I (see Fig. 18.3). Alternatively, a soft electrophysiology (EP) catheter (either a small transvenous catheter or a specialized catheter made for transesophageal pacing and recording) can be placed in the esophagus and connected to the ECG machine in a similar manner to obtain a recording of the left atrial signal.

A thorough history is also very important. Unfortunately, palpitations are a common complaint in children, especially among teenagers. Differentiation between tachyarrhythmias and sinus tachycardia due to other causes can be challenging. The onset and termination of tachycardia are important historic features. The onset of tachycardia frequently is described as sudden in both sinus tachycardia as well as tachyarrhythmias. The termination of tachycardia typically is gradual in sinus tachycardia. In a tachyarrhythmia, the termination may occur in a single beat. Dizziness can occur with both tachyarrhythmias and sinus tachycardia. If palpitations *precede* dizziness, this is more consistent with a tachyarrhythmia. If dizziness is the first symptom, a tachyarrhythmia is unlikely

Figure 18.3. ECG tracing obtained using atrial temporary pacing wires. The two atrial pacing wires are connected to the right arm (*white*) and left arm (*black*) leads giving a pure atrial signal in lead I (marked by *asterisk*). Using this tracing, it is possible to delineate the atrial signal from the QRS complex

to be the source of symptoms. Quantification of the heart rate also can be challenging to obtain from a history because it is infrequent that an actual pulse is taken during an episode. Asking the child or parent to tap with his or her hand to approximate the symptoms may be a beneficial tool to estimate heart rate. Heart rates that are faster than one is able to count should prompt evaluation for a tachyarrhythmia.

Many tachyarrhythmias only occur with exercise as the increased catecholamine state may enhance conduction in the AV node, making reentrant tachycardias more likely or enhancing automaticity. In these particular circumstances, performing an exercise treadmill test may be indicated to elicit an abnormal tachycardia. Several different protocols can be used depending on the particular type of exercise that causes the tachycardia. The typical continuous escalating protocol (Bruce protocol) may be used or modified to replicate the type of activity that triggers the tachyarrhythmia.

As many patients who have tachyarrhythmias have a normal resting ECG when not in tachycardia, a 24-hour cardioscan or Holter monitor that records all ECG activity continuously for a 24-hour period rarely is helpful in diagnosing tachyarrhythmias unless symptoms happen daily. The monitor may be worn for 48 hours or even longer, but once again it is only helpful if symptoms occur while the monitor is being worn.

If symptoms happen only occasionally, one of two types of event monitors may be prescribed. The first is a small recording device containing electrodes that has the capability of recording an ECG only when activated. When a patient feels symptoms, he or she places the device on the chest and activates it, which then creates a recording of the rhythm at that time. The recordings then can be transmitted electronically to obtain an ECG during the symptoms. A second type of event monitor is a looping recorder. This device is connected by ECG monitoring electrodes to the patient and continuously records the rhythm. When the recording switch is activated, it has the capability to go back and record ECG tracings several minutes prior to the activation as well as following the activation. It also can be programmed to automatically record the rhythm if the heart rate exceeds or drops below a certain set rate. The external loop recorder may have issues with compliance because the ECG electrodes often are irritating to the skin and must be changed on a regular basis. A different type of loop recorder actually may be implanted under the skin to continuously record the cardiac rhythm, thus avoiding the problem of constantly having ECG leads attached. It functions similar to an external loop recorder. The loop recorder can then be downloaded to obtain the rhythm tracings. This can be done with the same programmer used to interrogate a pacemaker or can be done via a unit placed in the patient's home. An implantable loop recorder can be useful in pediatric patients for determining the presence or absence of an arrhythmia during symptoms of syncope, near syncope, and palpitations when conventional diagnostic testing such as ECG, Holter monitoring, and/or external loop recording is inconclusive (7). The drawback is the necessity for a minor surgery to implant the device with the need to remove the monitor when it is no longer needed or when the battery life ends (typically around 3 years after implantation). Fortunately, implantable loop recorders are rarely indicated in pediatric patients and should be reserved for cases when it is critical to document the presence and/or characteristics of an arrhythmia. After documentation of the tachycardia, it is then possible to characterize further the arrhythmia and plan a strategy for therapy.

Characterization of Tachycardias

One method for categorizing tachyarrhythmias is to examine the width of the QRS complex and divide the tachyarrhythmias

into narrow complex and wide complex. In making this distinction, one must take into account the duration of the QRS, which depends on the patient's age and history of cardiovascular surgery. In general, neonates have shorter QRS durations than other age groups. In a child <1 year old, a QRS duration of more than 80 milliseconds (two boxes on a standard ECG) should be considered wide. It is always important to measure the QRS duration as a QRS duration of 100 milliseconds may look narrow to the naked eye on an electronic monitor tracing present at the bedside. In general, narrow complex tachycardia originates from an area above the ventricles. The differential diagnosis of wide complex tachycardia, including VT, is discussed later in this chapter.

Sinus Arrhythmia

Although named as an arrhythmia, this phenomenon is related to increasing amounts of vagal tone and is entirely normal. In sinus arrhythmia, the P wave axis remains normal, but the heart rate increases with inspiration and decreases with expiration. It may be more prominent in younger patients with faster heart rates and is present at some point during 24-hour monitoring in almost all children (8). This variation in rate rarely exceeds 100% (e.g., from a rate of 60 to 120 beats per minute); if it does, it may signify an abnormality.

Narrow Complex Tachycardias

Supraventricular tachycardia (SVT) is the most common sustained arrhythmia in children, with an estimated incidence from 1 in 25,000 to as high as 1 in 250 children (9). The most common age at presentation in childhood is within the first 2 months of life (10).

SVT is defined as an abnormally rapid rhythm that originates proximal to the bifurcation of the bundle of His, is caused by an abnormal mechanism (specifically excluding sinus tachycardia), and does not have flutter waves on the surface ECG. Although most patients with SVT have a structurally normal heart, 20% of patients have structural heart disease (11).

One method for subdividing narrow complex tachycardias is to examine the relationship between the QRS complex and the P wave on the ECG. To do this, a line is drawn halfway between two successive QRS complexes. If the P wave is buried in the QRS complex or is visualized prior to the line between the two consecutive QRS complexes, the tachycardia is considered to be a short RP tachycardia. If the P wave is visualized after this line, it is considered to be a long RP tachycardia. The description of specific types of long RP versus short RP tachycardias is listed in Table 18.2.

Accessory Pathway–Mediated Tachycardia

In the normal heart, the atria and ventricles are isolated electrically from each other by the fibrous annulus of the tricuspid and mitral valves. The only way for electrical impulses to pass from the atria to the ventricles is through the AV node, which penetrates through the central fibrous body to conduct electrical impulses. An accessory pathway is an additional electrical conduction pathway from the atria to the ventricles. This pathway results from a defect in the fibrous annulus as the embryonic atria and ventricles become electrically isolated. This process occurs in all fetuses during cardiac development but regresses in most cases. Persistence of one of these connections creates an accessory pathway. Accessory pathways are derived from either normal ventricular myocardium or specialized conduction tissue. Accessory pathways can conduct antegrade only (Mahaim fibers), both antegrade and

TABLE 18.2 Characteristics of Narrow Complex Tachycardia

SVT Type	Incessant/ Paroxysmal	P Wave Axis	RP Relationship	Adenosine Response	Reentrant or Automatic
AVN (typical)	P	LSRA	Short	Terminate	Reentrant
AVN (atypical)	I	LSRA	Long	Terminate	Reentrant
WPW	P/I	Not HRA	Short	Terminate	Reentrant
URAP	P/I	Not HRA	Short	Terminate	Reentrant
PJRT	I	LSRA	Long	Terminate	Reentrant
Mahaim	P	LSRA	Short	Terminate	Reentrant/auto
AET	P/I	Not HRA	Long (may Wenckebach)	None or term	Automatic

AVNRT, AV node reentry tachycardia; WPW, Wolff-Parkinson-White; URAP, unidirectional retrograde accessory pathway; PJRT, permanent form of junctional reciprocating tachycardia; AET, atrial ectopic tachycardia; NFAT, nonautomatic focal atrial tachycardia; JET, junctional ectopic tachycardia; HRA, high right atrium; LSRA, low septal right atrium.

retrograde (Wolff-Parkinson-White [WPW]), or retrograde only (unidirectional retrograde accessory pathway [URAP]).

There are two different mechanisms by which accessory pathways can cause SVT. In an *orthodromic* tachycardia, the conduction is antegrade through the AV node to the ventricle and then retrograde through the accessory pathway to the atrium (see Fig. 18.4A). This is the usual form of accessory

pathway-mediated tachycardia and results in a rapid rate with a narrow QRS complex. The other mechanism is termed *antidromic* tachycardia (see Fig. 18.4B). In this form of tachycardia, conduction is antegrade through the accessory pathway to the ventricle then retrograde through the AV node to the atrium and can only occur in accessory pathways with antegrade conduction. Because the activation of the ventricle is

Figure 18.4. A: Orthodromic SVT using an accessory pathway. The rate is around 320 beats per minute and the QRS morphology is narrow as the antegrade activation is through the AV node and the retrograde activation is through the accessory pathway. B: Antidromic SVT induced during an EP study. The QRS morphology is wide and has the same activation pattern as the manifest preexcitation on the ECG in sinus rhythm as the antegrade limb is through the accessory pathway.

through the accessory pathway and not the AV node, this type of tachycardia is always a wide complex tachycardia. The activation of the ventricle will have the same pattern as the pattern of preexcitation seen on the surface ECG in sinus rhythm. Of note, in both types of tachycardia all four components (ventricle, accessory pathway, atrium, and AV node) are critical for maintaining the reentrant tachycardia circuit, and the tachycardia may be terminated in any one of these four limbs.

Wolff-Parkinson-White

In 1930, Drs Wolff, Parkinson, and White described an ECG syndrome consisting of a functional bundle branch block and a short PR interval in healthy people with paroxysms of tachycardia (12). This syndrome now bears their names. WPW syndrome or ventricular preexcitation involves the combination of three findings: a PR interval shorter than normal for the patient's age, a slurred upstroke of the QRS complex (i.e., a delta wave), and a QRS complex of longer duration than normal for age (see Fig. 18.5). There also frequently are changes in the ST or T waves. These findings may not be found in all leads, and the midprecordial leads (V2–V4) may be the most sensitive. Other clues to the presence of WPW are left axis deviation, the absence of Q waves in lead V6, abnormally wide Q waves in the limb leads (a pseudoinfarction pattern), junctional escape beat seen with a different QRS morphology, and accentuation or loss of preexcitation with a premature atrial contraction (PAC). The EP definition of preexcitation, or WPW, is a His to ventricle (HV) interval of <35 milliseconds.

Its incidence is 0.1% to 0.3% among the general population and is more prevalent in men than women (13–15). However, the true incidence of WPW may be much higher because many patients are asymptomatic. Although asymptomatic patients do not technically meet the definition for WPW “syndrome” (because they do not have tachycardia), these patients are still labeled as having WPW, although a more correct description would be ventricular preexcitation.

WPW has a known association with congenital heart disease, ranging from 9% to 32% of patients, so an echocardiogram generally is indicated (10,16–18). The structural cardiac diseases known to be associated with WPW include Ebstein anomaly of the tricuspid valve, corrected transposition of the great arteries, and hypertrophic cardiomyopathy; noncardiac associations include glycogen storage disease and tuberous

sclerosis. The majority of WPW cases tend to be sporadic in nature, but in a small minority of these patients (3%), there is an identifiable affected first-degree relative, and familial cases have been reported (7p3 chromosomal association) (19). In addition, approximately 9% of WPW patients have more than one accessory pathway (20). The incidence of multiple pathways may be as high as 20% of patients who have underlying congenital heart disease (21).

WPW may participate in arrhythmic substrates in two different ways. The first is as one of the limbs in a reentrant SVT. The second is conduction to the ventricle during atrial fibrillation. Many patients will present with symptomatic SVT, but some will have WPW discovered on an ECG done for other reasons. However, a significant percentage of incidentally discovered patients with WPW will develop an arrhythmia—15% after a mean follow-up of 37.7 months in a large Italian study (22). In higher-risk groups (patients with rapidly conducting accessory pathways or multiple pathways), this figure may be as high as 44% (23). In a large study of military personnel followed over 20 years, 23% with constant preexcitation developed reentrant SVT compared to 8.3% who only exhibited intermittent preexcitation (24).

Episodes of SVT decrease in frequency over the first year of life in >90% of patients. However, tachycardia recurs in approximately 30% of them at an average age of 7 to 8 years (18). Furthermore, there is evidence that in the first year of life the accessory pathway loses anterograde conduction in as many as 40% of patients and SVT becomes noninducible in a similar percentage, suggesting loss of retrograde conduction as well (25). However, if a WPW pattern persists on ECG, there is up to a 29-fold increased chance of SVT recurrence, requiring additional antiarrhythmic therapy to control SVT (26). If SVT presents after an age of 1 year, >90% of patients will have a recurrence (27).

Patients with WPW rarely present with symptoms of heart failure from the hemodynamic effects of preexcitation alone. This is presumed to be because of dyssynchronous ventricular contraction associated with an extremely preexcited rhythm (28). In addition, there is an improvement in ejection fraction after ablation of septal accessory pathways in pediatric patients (29) as well as rapid normalization of ventricular function and reverse left ventricular remodeling after elimination of ventricular preexcitation in adult patients (30).

Patients with WPW are at risk of developing atrial fibrillation. There are two likely mechanisms of paroxysmal atrial

Figure 18.5. WPW with a shortened PR interval, widened QRS, and slurring of the upstroke of the QRS (Delta wave). Note the deep, wide Q wave in lead aVR (pseudoinfarction pattern) and the unusual appearance of the ST segments due to the preexcitation.

Figure 18.6. Atrial fibrillation in a patient with WPW. This creates an irregularly irregular wide complex tachycardia characteristic of this arrhythmia.

fibrillation in patients with WPW syndrome: one mechanism is reversible and directly related to the accessory pathway, while the other is intrinsic and accessory pathway-independent atrial vulnerability (31). Just as patients with multiple accessory pathways may be at a higher risk of SVT, they are also at a higher risk of atrial fibrillation (32). Atrial fibrillation as a presenting symptom occurs rarely, with an incidence of 6% in one study (33). Atrial fibrillation in WPW presents as a characteristic irregular wide complex tachycardia (see Fig. 18.6). This feature separates this arrhythmia from most VTs, which have a relatively constant cycle length. Rapid conduction through the accessory pathway may lead to VT or fibrillation with resultant hemodynamic collapse (34). Adenosine, digoxin, and calcium channel blockers typically are contraindicated in WPW patients in atrial fibrillation because they promote conduction through the accessory pathway rather than the AV node, precipitating ventricular arrhythmias. Direct current cardioversion is the preferred therapy, especially in the presence of rapid conduction down the accessory pathway.

The incidence of both malignant WPW syndrome resulting in cardiac arrest and WPW causing SVT is higher in patients with syncope than in patients who are otherwise asymptomatic (35). Therefore, syncope in a patient with WPW should prompt rapid referral for further diagnostic testing.

Risk Stratification

Risk stratification may be beneficial, even in asymptomatic individuals, because sudden cardiac death may be the first presentation of WPW syndrome in up to 1.4% of patients, according to an Italian study (22). However, other studies from the United States indicate that the overall sudden cardiac death rate is low (on the order of 0.0015 per patient-year) and that sudden cardiac death is extremely rare in patients who are asymptomatic at diagnosis (36). Rapid antegrade conduction through an accessory pathway is the primary risk factor for sudden cardiac death. Tachyarrhythmia inducibility and multiple accessory pathways also are risk factors for potentially life-threatening arrhythmic events (34). The risk of sudden cardiac death in patients younger than 8 years old is very small and is minimal in patients younger than 5. As invasive and noninvasive testing in this young age group may present challenges, it is acceptable to wait until ages 5 to 8 years to perform risk stratification. In a study by Bromberg et al. (37), cardiac arrest was the only distinguishing clinical

feature between high and low-risk groups and the first manifestation in 80% of the children of an accessory pathway that can precipitate a life-threatening arrhythmia. As patient history is not helpful in distinguishing high-risk groups in WPW, other methods of risk stratification need to be performed.

One method of stratifying patients with WPW by risk is to perform an exercise treadmill test. If there is loss of preexcitation, this suggests a low-risk accessory pathway (38,39) (see Fig. 18.7). The loss of preexcitation should occur in a single beat, rather than gradually, in order to classify the pathway as low risk based on the treadmill test (40). Although, intermittent preexcitation seen either on an ECG or 24-hour cardio monitor is a predictor of poor anterograde conduction through the accessory pathway, it has been observed in some patients with cardiac arrest (41).

The test that has held up as the best predictor for patients at risk for sudden death is the measurement of the shortest pre-excited RR interval (SPERRI) during atrial fibrillation, which can be performed if a patient presents in atrial fibrillation. Atrial fibrillation also can be induced by rapid atrial pacing from a transesophageal pacing probe (42) or by using a single transvenous pacing catheter placed in the atrium. During atrial fibrillation, two QRS complexes that show preexcitation are located and the *shortest* interval between two consecutive beats is measured in milliseconds. A SPERRI of 220 to 250 milliseconds and especially <220 milliseconds is more commonly seen in patients with WPW who have experienced cardiac arrest (37,43). These patients are candidates for ablation, or medical therapy to alter the conduction properties of the accessory pathway if ablation is not possible. However, an EP study is more useful to identify those at low risk of sudden death because the overall risk of sudden death in WPW is low. As many accessory pathways, particularly septal pathways, may

Figure 18.7. Loss of preexcitation in a single beat during an exercise treadmill test indicating a low-risk accessory pathway. The asterisk indicates the beat with loss of preexcitation.

Figure 18.8. PJRT with deeply negative P waves in leads II, III, and aVF.

augment their conduction in the presence of catecholamines, it may be beneficial to perform the risk assessment while using an isoproterenol infusion (44). It is controversial whether the risks of performing an ablation of an accessory pathway (particularly one located in a high-risk location) outweigh the true risk of an arrhythmic sudden death, but eliminating conduction via catheter-based technology should be strongly considered in rapidly conducting pathways.

Unidirectional Retrograde Accessory Pathway

An accessory pathway may be present even when the surface ECG shows no overt manifestation. These pathways may conduct retrograde only (URAP) and, therefore, can be the cause of a reentrant SVT. The therapy and management of these accessory pathways are similar to those for WPW, but because there is no antegrade conduction, these patients are not at the same risk for sudden death from rapid conduction in atrial fibrillation.

Treatment of Supraventricular Arrhythmias

Treatment of supraventricular arrhythmias depends on patient age, severity of symptoms, spontaneous termination, length of symptoms, presence of other cardiac defects, and number of episodes. Medical treatment typically is effective, but does not address the underlying cause. Catheter ablation, particularly in patients older than 5 years of age should be considered. Ablation indications are discussed in another chapter in this book (see Chapter 17).

Permanent Junctional Reciprocating Tachycardia

A unique type of accessory pathway-mediated tachycardia is the permanent form of junctional reciprocating tachycardia. Initially, this tachycardia was thought to arise from the AV junction and thus was named a junctional reciprocating tachycardia. Later investigation actually showed this to be a slowly conducting accessory pathway, but the name permanent junctional reciprocating tachycardia (PJRT) has persisted. A PJRT fiber typically is located in the posterior septum on the right side of the heart, although fibers may be located in the midseptum or even on the left side of the heart. Because these fibers conduct slowly, the tachycardia presents as a long RP

where the P wave is visible easily on the surface ECG. The ECG in tachycardia has a classic morphology with deeply negative P waves in the inferior leads, II, III, and aVF (see Fig. 18.8). This type of tachycardia frequently is present immediately after birth but because of its relatively slow rate (150 beats per minute) may not be appreciated on routine examinations in newborns and infants. PJRT also tends to be an incessant tachycardia and may lead to a tachycardia-induced cardiomyopathy if left untreated (45).

Mahaim Fibers

Mahaim fibers are special types of accessory pathways connecting the atria to the ventricles bypassing at least part of the AV node. Descriptions of these fibers identify them as connecting either the atria to the fascicles (atriofascicular fibers), the bundle of His to the ventricles, the fascicles to the ventricles, or the atria to the bundle of His. These fibers generally are located on the right ventricular side of the heart but occur rarely on the left ventricular side. Because of their right-sided location, during tachycardia the patient's ECG has a left bundle branch block pattern. These pathways have unique properties similar to those of the AV node in that they often possess decremental conduction (conduct slower at a faster rate) and are typically catecholamine sensitive. Unlike most other accessory pathways, some of these fibers may have automaticity and are capable of depolarizing spontaneously (46). Tachycardia may result from this spontaneous depolarization or from reentrant tachycardia using the Mahaim fiber as the antegrade limb and the AV node as the retrograde limb. On the surface ECG in normal sinus rhythm, they often present as a normal PR interval with a slurred upstroke of the QRS (pseudo-preexcitation) resulting from ventricular depolarization through the Mahaim fiber (47). These fibers often times have only intermittent conduction, and although Mahaim fibers conduct antegrade, their risk for rapid ventricular conduction during atrial fibrillation likely is not present and therefore does not present a risk for sudden cardiac death.

Automatic Focus (Atrial Ectopic Tachycardia)

Atrial ectopic tachycardia (also known as ectopic atrial tachycardia) results when an abnormal focus of cells distinct from the sinus node in the atrium spontaneously depolarizes faster

Figure 18.9. These two irregular rhythms from different patients have a similar rate, but the underlying mechanism is different. The **top strip** represents an atrial tachycardia as there is a clear change in the P-wave axis from the normal sinus beats. The **bottom strip** represents a sinus arrhythmia which is a normal finding particularly in pediatrics with acceleration during inspiration and slowing during expiration with no change in the P wave axis or morphology.

than the underlying sinus node. AET can be incessant, and its rate may increase or decrease based on sympathetic tone and catecholamine state. Distinct P waves typically are visible, although the P waves may have an abnormal morphology or be notched (see Fig. 18.9). First-degree AV block or even Mobitz type I second-degree AV block (Wenckebach) may be present and provide clues about the presence of an abnormal tachycardia (48). The P waves at the onset of tachycardia are similar to the morphology of subsequent P waves in the tachycardia. Often times, the focus of the AET is in the right atrium along the crista terminalis or in the right atrial appendage (49). The P-wave axis in tachycardia frequently is abnormal on the surface ECG, unless its origin is near the sinus node or right upper pulmonary vein. When the focus is near the sinus node it shows as an upright P wave in lead I and aVF (similar to normal sinus rhythm), but the P wave frequently is negative (rather than biphasic) in lead VI, thus providing a clue to the presence of an ectopic atrial focus. In up to one-third of cases, multiple atrial foci may be the source of the tachycardia (50). Automatic focus atrial tachycardias account for 4% to 6% of SVT and are often incessant; these too can be associated with significant cardiac dysfunction (51).

The atrial rate in AET frequently displays periods of warming up and cooling down rather than a paroxysmal onset and termination. Often, this tachycardia appears initially as a wide QRS tachycardia. This occurs because of the refractory periods of the bundle branches that usually accommodate the faster rate and normalize. Adenosine can be useful in diagnosing this arrhythmia because it blocks the AV node without affecting the ectopic focus, and the arrhythmia generally does not terminate. However, some foci are adenosine sensitive, particularly those originating around the AV node (52). Cardioversion and overdrive pacing may temporarily suppress AET only to have it quickly resume its initial rate at least in part because of its catecholamine sensitivity.

Spontaneous resolution of AET is unlikely in children older than 3 years (53). For this reason, cardiac catheterization with ablation techniques generally is recognized as first-line therapy. However, in children younger than 6 months, there is a high incidence of spontaneous resolution of tachycardia with a low long-term incidence of recurrence. It is advisable to attempt medical control in these patients until the tachycardia resolves if the tachycardia is sustained or very rapid. Slower atrial tachycardias (<220 beats per minute) that are not incessant may not require therapy if the ventricular function is normal, although these patients require close follow-up.

Some arrhythmias that are difficult to control with medical therapy are caused by hamartomas within the myocardium. If reasonable control of the arrhythmia can be obtained with medication, they frequently will regress (54). In rare cases, when control cannot be achieved with maximal medication, the patient may require surgical excision of the tumor (55). These tumors frequently are visible to the naked eye as pale colored areas of the myocardium and can be excised.

Nonautomatic Focal Atrial Tachycardia

Nonautomatic focal atrial tachycardia (NAFAT) results from a small reentrant circuit within the atrium (i.e., micro-reentrant tachycardia) (56). This type of tachycardia, like other reentrant tachycardias, can be reproducibly induced with programmed atrial stimulation and can be terminated with adenosine. It commonly is located in the right atrium in patients with either normal or structurally diseased hearts (57). Although distinct from AET, its management is similar and is very amenable to ablation.

Chaotic Atrial Tachycardia

Chaotic atrial tachycardia or multifocal atrial tachycardia is a type of atrial tachycardia with multiple foci, which results in three or more P wave morphologies on the ECG. It has been described in children with otherwise normal hearts as well as in patients with acute viral bronchiolitis or advanced pulmonary disease. Because of the rapid chaotic nature of the tachycardia, it may be difficult to distinguish from atrial fibrillation. This type of tachycardia is difficult to treat and can be refractory to pace termination, DC cardioversion, and adenosine. This type of tachycardia is not amenable to ablation and typically is treated with medical therapy using Vaughn Williams class IA, IC, or III agents (see Table 18.3).

Junctional Ectopic Tachycardia

JET is an automatic focus tachycardia arising within or immediately adjacent to the AV junction. This tachycardia has a relatively high familial incidence. This tachycardia is, by definition, generally a narrow complex tachycardia with a QRS morphology identical to the QRS morphology in sinus rhythm (see Fig. 18.10). The classic description of this tachycardia is that there is no association between the P waves and the QRS complexes on the ECG. In reality, this tachycardia has all Junctional–Atrial (J–A) relationships from 1 to 1, to J–A Wenckebach, to no relationship. Retrograde P waves often are visualized in the terminal portion of the QRS. With adenosine, there may be loss of the retrograde conduction, resulting in dissociation of the P wave and the QRS. JET has two different forms: idiopathic JET, which is observed in a structurally normal heart, and postoperative JET.

Postoperative JET occurs in up to 6% of patients undergoing cardiac surgery and is seen more frequently with use of inotropic agents such as dopamine (58). Congenital JET is one of the rarest forms of SVT in infants and also one of the most difficult to treat. Congenital JET is presumed to be present from birth but may not be identified until months or years later. Patients with congenital JET have a wide range of clinical presentations. Patients with JET presenting at or younger than 6 months of age are more likely to have incessant JET

TABLE 18.3 Vaughan-Williams Classification**Class I**

- Block sodium channels
- Decrease speed of depolarization
- Slow conduction velocity
- Subdivided into Ia, Ib, and Ic

Class II

- Beta-blocking drugs
- Block adrenergic receptors
- Decrease sympathetic tone

Class III

- Block potassium channels
- Increase action potential duration

Class IV

- Calcium channel blockers
- Affect mainly SA and AV nodes
- Direct membrane effect

Class V

- Digitalis agents
- Affect mainly SA and AV nodes
- Act indirectly by increasing vagal tone

and to have faster JET rates, and the mortality rate in this population is approximately 4% (59). With current medical, ablative, and device therapies, the majority of patients have a good outcome.

Atrial Flutter

Atrial flutter is an uncommon arrhythmia in the pediatric population. It typically occurs in newborn infants and postoperatively in congenital heart disease patients. Newborn infants present within the first 2 days of life with tachycardia and frequently have signs of congestive heart failure (60). The ECG for these patients has the typical saw-toothed flutter waves (see Fig. 18.11) with atrial rates between 300 and 600 beats per minute and variable conduction to the ventricles. If the flutter waves cannot be distinguished easily on the ECG, adenosine can be given to reveal the flutter waves. Treatment is direct current-synchronized cardioversion with 0.5 to 1 J/kg. Atrial overdrive pacing also can be used if the atrial rate is slow, but this is more difficult to perform. Newborns with atrial flutter typically have no structural heart disease and have no further problems after successful cardioversion. A 24-hour cardioscan should be placed after cardioversion to rule out the rare reentrant tachycardias or atrial tachycardias that initiated the atrial flutter. Generally, the atrial flutter will not recur, and if no evidence of other arrhythmias is present, these infants do not require antiarrhythmic therapy and follow-up is not necessary (61).

Atrial Fibrillation

Atrial fibrillation is an uncommon arrhythmia in the pediatric population but is important to recognize. Atrial fibrillation presents as an irregularly irregular rhythm with the same QRS morphology as in sinus rhythm (see Fig. 18.12). Although P waves frequently are not visible in atrial fibrillation, they may be seen in patients with coarse atrial fibrillation. Atrial fibrillation can occur in the context of WPW or following extensive surgery involving the atrium such as a total cavopulmonary connection or atrial switch operation (Mustard or Senning). Patients who present with atrial fibrillation without evidence of structural heart disease warrant evaluation for other arrhythmias, such as reentrant SVT, that degenerate

Figure 18.10. Slow JET. Note the narrow QRS morphology similar to sinus rhythm. The asterisks denote the underlying sinus rhythm P waves. There is no relationship between the P waves and the QRS, except for a single P wave that falls in a period where the AV node is not refractory from the ectopic junctional rhythm and is therefore able to conduct to the ventricle (sinus capture beat) denoted by the arrow. These sinus capture beats likely indicate that the underlying conduction in the AV node is intact.

Figure 18.11. Neonatal atrial flutter with a saw-toothed pattern and an atrial rate of around 375 beats per minute. There is variable conduction through the AV node to the ventricles with predominantly 2:1 block, but also 3:1 block noted by the arrows.

into atrial fibrillation or an underlying channelopathy. If none are found, the problem could simply be primary or lone atrial fibrillation, which has been described in the late teenage years (62). Occasionally, atrial fibrillation may be the initial presentation of hyperthyroidism, myocarditis, or digoxin toxicity.

One of the initial therapies for chronic atrial fibrillation was ablation of the AV node with implantation of a permanent pacemaker. Because of the permanent loss of AV synchrony combined with the long-term need and dependence on a pacemaker as well as chronic anticoagulation, this therapy should be reserved only

for the most refractory and symptomatic cases of atrial fibrillation that have failed to respond to multiple medical therapies.

Intraatrial Reentrant Tachycardia

Intraatrial reentrant tachycardia (IART) occurs in patients who have undergone previous cardiac surgery either on or through their atria and are left with extensive scarring. This unique form of arrhythmia is similar to atrial flutter. It tends to have slower

Figure 18.12. Atrial fibrillation with an irregularly irregular rhythm. This is coarse atrial fibrillation with visible atrial activity that is disorganized and chaotic. Some of the beats (noted by arrows) are conducted aberrantly through the AV node causing the QRS morphology to change.

Figure 18.13. Intra-atrial reentry tachycardia. The P waves of the tachycardia are frequently buried in the T waves or the QRS when the tachycardia has 2:1 conduction, especially in the presence of a bundle branch block. Note the flat isoelectric baseline between the P waves and the relatively small amplitude compared to atrial flutter.

rates than atrial flutter, with atrial rates in the 140 to 200 beat per minute range. The ECG is different because there tends to be an isoelectric baseline between two consecutive P waves, unlike atrial flutter, where constant atrial activity creates the sawtoothed pattern (see Fig. 18.13). The P waves in IART may be

very small and are often missed, particularly if they are buried within the QRS complex or the T wave. Adenosine can be used to unmask this type of tachycardia. Because this type of tachycardia often occurs in patients with underlying sinus node dysfunction (SND), patients presenting with an unusually fast heart rate (>100 beats per minute) should be carefully examined for the presence of this arrhythmia. There is utility in placing epicardial ablation lesions in strategic positions (the so-called maze or maze-Cox III procedure) to prevent IART, and atrial fibrillation in pediatric patients and adults with congenital heart disease. This is particularly useful in patients who have had extensive atrial operations such as the Fontan procedure. Long linear probes can quickly form deep uniform lesions without the need to arrest the heart or place the patient on cardiopulmonary bypass. These lesions appear to have a relatively good long-term success even in the most complicated patients. For patients with atrial arrhythmias having a Fontan revision, there is up to a 76% recurrence without the placement of intraoperative ablation lesions (63). Physicians at most large centers routinely place ablation lesions (maze procedure) when doing a Fontan conversion. The late recurrence of atrial arrhythmias is only 13% to 22% (64,65).

Wide Complex Tachycardias

Wide complex tachycardias should be assumed to be VT until proven otherwise. However, there are several situations when a wide complex tachycardia may be supraventricular in origin (see Fig. 18.14). The most common scenario involves the presence of a SVT with aberrancy. With rapid onset of a tachycardia, either the left or right bundle branch may be

Figure 18.14. Diagrammatic representation of tachycardias with prolonged (wide) QRS. Such tachycardias may be due to (A) orthodromic reciprocating tachycardia (ORT) with bundle branch block (BBB), (B) antidromic tachycardia using an accessory AV connection (ART), (C) primary atrial tachycardia with BBB, (D) atrio-ventricular nodal reentry tachycardia (AVNRT) with a bystander accessory connection (AC), (E) tachycardia using a Mahaim fiber, or (F) ventricular tachycardia. Despite the diversity of mechanisms, ventricular tachycardia should be assumed until or unless additional data to the contrary are available.

Figure 18.15. The initial portion of the tracing shows a wide complex tachycardia that subsequently changes to a narrow complex tachycardia at exactly the same rate. This is all SVT and not two different arrhythmias. The initial portion is aberrantly conducted. As the AV node and bundle branches accommodate to the faster rate, the SVT becomes narrow.

refractory and not able to conduct impulses. This results in a wide complex tachycardia on the ECG. A left bundle branch block pattern of aberrancy is much more common in neonates, while a right bundle branch block pattern is more common in children and adolescents. Frequently, the bundle will accommodate the tachycardia, and the QRS complex will become narrow (see Fig. 18.15). A second common scenario occurs when a SVT presents with a wide complex in the presence of an underlying bundle branch block on a baseline ECG or in the presence of preexcitation from WPW.

Most wide complex tachycardias except for ventricular fibrillation are relatively regular tachycardias. When an

irregular wide complex tachycardia is present, the possibility that this is atrial in origin should be raised.

Ventricular Tachycardia

VT is defined as three or more premature ventricular contractions (PVCs) in a row at a rate faster than 120 beats per minute. Slower rates, within around 10% to 20% of the underlying sinus rate, are referred to as accelerated ventricular rhythms and typically have a benign prognosis and treatment typically is not necessary (66) (see Fig. 18.16). A hallmark

Figure 18.16. Accelerated ventricular rhythm. There is a wide complex rhythm that is within 20% of the underlying sinus rate and gradually overtakes the underlying sinus rhythm. There is no relationship between the ventricles and the atria (so-called VA dissociation) which distinguishes this as a ventricular arrhythmia (the arrows designate P waves that have no relationship to the tachycardia). This variant has a benign prognosis.

Figure 18.17. Ventricular tachycardia in a neonate. Note the relatively narrow complexes that are different from sinus beats and retrograde P waves in the initial portion of the tracing.

of VT is that the QRS complex is different than that of the sinus QRS complex but does not have to be wide. In infants younger than 2 years old, the QRS duration in VT can be as short as 0.06 seconds, and the rate can be as fast as 500 beats per minute (see Fig. 18.17). VT rarely can present as a narrow complex tachycardia in older patients as well. This occurs when the focus of the tachycardia is in close proximity to or contained within the normal conduction system. Most VTs, particularly in patients with structural heart disease, are reentrant in nature, although automatic foci occur in patients with structurally normal hearts.

In the normal pediatric population, spontaneous VT has an approximate incidence of 1/100,000 in the childhood years and may present any time between infancy and young adulthood (67). However, short episodes of VT can occur in up to 3% of otherwise healthy teenagers on routine Holter monitoring (68). In comparison to patients with structural heart disease or cardiomyopathy, patients with normal cardiac anatomy and function generally have a benign course. The presence of underlying heart disease, presence of symptoms, rapid rate of VT, and exacerbation of VT with exercise are risk factors for adverse events in nonischemic VT in children. Control of arrhythmias by ablation or antiarrhythmic medications may be indicated in this population (69). The chance of resolution is higher when the onset occurs during the first year of life (resolution in about 90% of patients) compared with onset beyond the first year of life to 15 years of age (resolution in about 50%). The clinical profile is more favorable for patients with right-sided VT (resolution in 76% and symptoms in 25%) compared with patients with left-sided VT (resolution in only 37% and symptoms in 67%) (70).

Two forms of VT are thought to be benign variants—right ventricular outflow tract tachycardia (left bundle branch block, inferior QRS axis on ECG) and idiopathic left VT (right bundle branch block, superior QRS axis on ECG). These tachycardias tend to be responsive to verapamil. The benign variant of VT originates from the right ventricular outflow tract in around 50% of patients (71). It is important to recognize underlying precipitating causes of VT—such as long QT syndrome,

arrhythmogenic right ventricular cardiomyopathy (ARVC), anomalous coronary arteries, and hypertrophic cardiomyopathy—because these patients may be at higher risk for sudden death. An echocardiogram is indicated in all patients with VT, and further imaging, including magnetic resonance imaging or cardiac catheterization, may be indicated in cases with a higher index of suspicion for underlying pathology.

More than 50% of pediatric patients with symptomatic or sustained VT have underlying structural heart disease, and another 25% may have at least subtle evidence of myopathy (72). Ventricular tachyarrhythmias in young infants may be associated with myocarditis, prolonged QT syndrome, severe electrolyte disturbances, or small hamartomas within the ventricular myocardium. In older children, VT may be associated with myocarditis, prolonged QT syndrome, medication overdose or toxicity, various forms of cardiomyopathy, arrhythmogenic right ventricular dysplasia, coronary artery abnormalities, and congenital heart disease both before and after surgery.

Patients with sustained or hemodynamically unstable ventricular arrhythmias or resuscitated sudden death episodes generally require placement of an implantable cardioverter defibrillator (ICD).

Torsades de pointes (also known as torsades) is an uncommon form of polymorphic VT with a characteristic twisting of the QRS complex around the isoelectric baseline (see Fig. 18.18). It commonly occurs in the presence of a channelopathy, such as *Brugada syndrome* or *long QT syndrome* (congenital or drug related), but may be associated with electrolyte abnormalities (particularly hypokalemia or hypomagnesemia), acid-base disturbances, endocrine disorders such as hypothyroidism, hyperparathyroidism or pheochromocytoma, myocardial ischemia, and myocarditis. Episodes typically are short lived and paradoxical and terminate spontaneously. However, longer episodes may progress to ventricular fibrillation and result in rapid hemodynamic compromise and sudden cardiac death (73). This tachycardia is unique in that it may respond to treatment with either isoproterenol or magnesium.

Figure 18.18. Torsades de pointes with its rapid polymorphic nature, and shifting of the QRS axis rapidly around an isoelectric baseline.

Tachycardia-Induced Cardiomyopathy

Although arrhythmias frequently occur in the context of depressed ventricular function, occasionally the *primary* cause of ventricular dysfunction is an arrhythmia. The ventricular dysfunction may be so severe that these patients may be listed for heart transplantation. One study showed that an incessant atrial tachycardia was present in 17% of patients listed for cardiac transplantation and accounted for 37% of patients initially diagnosed with idiopathic cardiomyopathy (74). The specific mechanisms of ventricular dysfunction secondary to tachyarrhythmias are poorly understood, but the arrhythmia typically is incessant. The minimum duration or heart rate necessary to develop dysfunction is unknown. Most studies suggest that patients who develop tachycardia-induced cardiomyopathy have heart rates >140 beats per minute (75). The origin of the tachycardia may be atrial or ventricular and may have an automatic focus or reentrant mechanism. SVTs are the most common cause of tachycardia-induced cardiomyopathy (76), although incessant ventricular arrhythmias may also result in cardiomyopathy. Ventricular rhythms causing cardiomyopathy are usually of automatic focus and frequently originate from the right or left ventricular outflow tract (77). Once an arrhythmia-causing tachycardia-induced cardiomyopathy is under control by either medication or catheter ablation, ventricular function typically normalizes. Many patients show a marked improvement as soon as 3 weeks after normalization of heart rate, although it may take up to 21 months to see a full recovery (78).

Premature Atrial Contractions

A PAC or supraventricular premature beat is a depolarization of atrial tissue that is distinct from sinus node tissue and manifests on ECG as a premature P wave. In most instances, it has a different morphology and axis from those of the sinus P waves. Most PACs are conducted to the ventricles with a normal QRS. Because the premature P wave occurs earlier and earlier, conduction to the ventricles may occur with a different QRS morphology than sinus rhythm (i.e., aberrantly conducted PAC). This occurrence may simulate a PVC. For any early QRS that has morphology different than that of the sinus beats, the preceding T wave should be examined carefully for a hidden

P wave. Occasionally, a premature P wave may occur so early that it results in no conduction to the ventricles. This situation may simulate sinus bradycardia because the premature P wave may conduct into the sinus node, delaying the next expected sinus impulse. In situations of paroxysmal bradycardia, especially those in which conducted PACs are on the same tracing, the T wave should also be searched carefully for the presence of hidden P waves. This phenomenon is especially common in newborn infants. Many tracings similar to the one in Figure 18.19 are interpreted as multiform PVCs with PACs and sinus bradycardia, when in fact most of these patients have only PACs, some of which conduct aberrantly and some of which block. PACs are common in the pediatric population. More than half of children have at least one PAC in a 24-hour monitoring period, and PACs occur more often in patients as they progress through their teenage years (8). Isolated PACs are benign and require further evaluation. If frequent PACs are noted on an

Figure 18.19. Premature atrial complexes are noted by the arrows. The first two PACs do not conduct to the ventricle (block). The next four complexes conduct to the ventricle but do not have a normal-appearing QRS (aberrantly conducted). The appearance of the aberrancy varies having both a left and a right bundle branch block morphology.

ECG or on monitoring strips, a 24-hour cardioscan monitor should be placed to exclude episodes of atrial tachycardia.

Premature Ventricular Contractions

A PVC is a premature QRS complex that does not have the same morphology as the sinus complex and is not preceded by a P wave. Especially in infants, PVCs may not have a broad QRS complex, but they have a morphology different than that of the sinus QRS. If all PVCs have similar morphology, they are referred to as uniform; if they have more than one morphology, they are called multiform. A ventricular couplet is defined as two PVCs in a row. Bigeminy is an alternating rhythm in which every other beat is a PVC, and trigeminy is when every third beat is a PVC.

Most children with PVCs have structurally normal hearts, and 40% of otherwise normal children may have PVCs seen on Holter monitoring (79). PVCs are multiform in up to 25% of patients, but there is no difference in prognosis from uniform PVCs (69). If the heart is completely normal, the prognosis for most children with uniform PVCs is good, and the condition is entirely benign. Although less well studied, the prognosis for uniform ventricular couplets is probably the same as for isolated PVCs. PVCs may spontaneously disappear, and PVCs with a right bundle branch block morphology may have a higher chance of resolution than PVCs with a left bundle branch block morphology (80). Rare cases of ventricular dysfunction occur as a direct result of PVCs in adults; with a PVC burden of >24%, this phenomenon is very rare in pediatrics (81).

Other factors that may be related to tachycardia-induced ventricular dysfunction are male gender, persistence of PVCs throughout the day, and the presence of repetitive monomorphic VT (82). If the history, physical examination, ECG (other than the rhythm), and echocardiogram are normal and the 24-hour cardioscan monitor shows only uniform PVCs and/or couplets, there is no need for medical therapy in these patients. It is prudent to repeat the cardioscan once after the initial evaluation to ensure that the ectopy has not changed or progressed. If a patient wishes to participate in competitive sports, an exercise treadmill test may be useful to determine the response of the ectopy to exercise.

Occasionally, PVCs are associated with long QT syndrome, myocarditis, hypertrophic cardiomyopathy, and congenital heart disease before or after surgery. Often in these patients, the resting ECG is abnormal, the ectopy is frequent (>1,000 PVCs an hour), or the PVCs are multiform. Closer surveillance is required in these patients, and they may require further evaluation.

Postoperative Arrhythmias

Hemodynamically significant postoperative arrhythmias are a frequent complication of pediatric cardiac surgery, occurring in about 15% of patients, with younger age and longer bypass

and cross-clamp times being risk factors for arrhythmia (83). JET and SVT are the most common postoperative arrhythmias (84). These arrhythmias may be transient and directly related to the cardiac surgery but also may be related to the underlying cardiac condition. Arrhythmias occurring more than 3 to 4 days following cardiac surgery may be an issue in the long-term care of these patients.

TREATMENT

All arrhythmias are mediated through the cardiac action potential. Antiarrhythmic medications affect the shape of the intracardiac action potential. They work by altering ion channels or blocking receptors. The Vaughan-Williams classification system was developed to help categorize antiarrhythmic drugs (85). This system organizes drugs based on their major mechanism of action—where they affect the cardiac cell membrane and subsequently the cardiac action potential (see Table 18.3). Changes in the action potential may change the conduction velocity, refractoriness, or automaticity (see Table 18.4).

Class I

Class I agents affect the sodium channels. They are divided into three categories: Ia, Ib, and Ic based on the effect they have on the action potential (see Fig. 18.20).

Class Ia agents slow the upstroke of the action potential, therefore prolonging its duration. This effect decreases conductivity and increases refractoriness.

Procainamide is a class Ia agent that suppresses normal and abnormal automaticity and slows conduction in accessory pathways in addition to being mildly vagolytic. Procainamide alters the ECG by increasing PR interval, QRS duration, and QT interval. It is metabolized approximately 35% by the liver, producing *N*-acetylprocainamide (NAPA), which prolongs the QT interval. The production of NAPA varies and is determined genetically. The other 65% is excreted by the kidneys. The therapeutic range is 4 to 12 mg/mL. NAPA levels have been measured in the past but have minimal therapeutic significance. Amiodarone and ranitidine increase procainamide levels. The intravenous dosage is a bolus of 10 to 15 mg/kg with close blood pressure monitoring. A continuous infusion of 30 to 80 micrograms (mcg)/kg/min can be employed. High doses have a negative inotropic effect, and caution should be exercised in patients with a prolonged QT interval, Brugada syndrome, left ventricular dysfunction, or sinus dysfunction. Because of this, procainamide generally is not a first-line agent. It can be used to treat supraventricular as well as VT if the tachycardia does not break with adenosine or immediately recurs after conversion. It also can be used in atrial fibrillation and atrial flutter. It is safe to use in neonates, but doses may need to be reduced in premature infants and those with renal dysfunction (86).

Figure 18.20. Changes in the action potential seen with Vaughan-Williams class I medications.

Class Ib agents have minimal effect on the upstroke of the action potential but do shorten its duration, which decreases refractoriness. Lidocaine is a Ib agent that inhibits fast inward sodium current, which primarily affects the ventricular myocardium. It shortens the action potential with no effect on QRS duration in sinus rhythm. It is highly selective for depressed myocardial tissue. The half-life is 5 to 10 minutes, and hypokalemia can decrease its effect. The typical loading dose of 1 mg/kg and infusion rate of 20 to 50 mg/kg/min can be titrated to achieve a therapeutic range of 1.5 to 5 mg/mL. Although not included in the 2010 Pediatric Advanced Life Support (PALS) guidelines, it may be useful in VT. Side effects include vertigo, tremor, seizures, obtundation, and bradycardia (in patients with SND). The hemodynamic effect is minimal at standard doses.

Unlike lidocaine, mexiletine is available in oral form. Outside of treatment for long QT syndrome, mexiletine is used only for frequent PVCs that cause symptoms or in patients with triggered VT (87). It rarely suppresses sustained VT and has prominent central nervous system side effects.

Class Ic drugs cause a marked slowing of upstroke of the action potential with minimal effect on the action potential duration. This results in a marked decrease in conductivity with little effect on refractoriness. The most commonly used agents are flecainide and propafenone.

Flecainide is a Ic agent that shortens conduction velocity with little effect on the sinus node but may exacerbate bradycardia in patients with SND. It is a pronounced negative inotropic agent. ECG effects include prolonging the PR and QRS intervals with minimal effect on the QT interval. The half-life changes with age: 12 hours in children <1 year old and >12 years old and 8 hours in children 1 to 12 years of age. Dairy products interfere with absorption, and patients may become toxic if dairy products are removed from their diet. Flecainide is 75% metabolized by the liver and 25% excreted by the kidneys. A therapeutic level is 0.2 to 1 mg/mL. QRS widening is infrequently seen at a therapeutic concentration and if present should warrant immediate evaluation for a high flecainide level. It is used in PJRT, AET, and SVT. Side effects include blurry vision (the most common side effect), dizziness, headache, fatigue, tremor, nausea, vomiting, and anorexia. It should be used with caution in patients with structural heart disease or primary cardiomyopathies. Severe proarrhythmia occurs in 1% to 3% of patients with abnormal hearts, and inpatient telemetry monitoring should be considered when initiating flecainide.

Class II

Beta-blockers have evolved over the years with the advent of newer and more selective agents. The first-generation beta-blockers are nonselective for beta-1 (predominantly located in the heart) and beta-2 (predominantly located in bronchial smooth cells) receptors and include propranolol and nadolol. Second-generation beta-blockers have relative selectivity for beta-1 receptors and include metoprolol, atenolol, and esmolol. Third-generation beta-blockers are selective or nonselective with potentially important ancillary properties and include carvedilol, which has the additional property of being an alpha-blocker that causes vasodilation.

Propranolol is a nonselective beta-blocker. In addition to its beta-blocking effects, it may have some direct effect on cell membrane stabilization. It is used in SVT, in ventricular arrhythmias (especially those that are catecholamine induced), and in atrial flutter or fibrillation to slow the ventricular response. More data exist regarding use in infancy, and there is a commercially available liquid preparation. Because of its rapid metabolism, it should be given 3 to 4 times a day or in a long-acting formulation.

Side effects include exacerbation of bronchospasm, hypoglycemia, depression, insomnia, fatigue, personality changes including aggression, and nightmares.

Nadolol is another nonselective beta-blocker that is similar in action to propranolol, but it has a preference for beta-1 receptors. It has a half-life of almost 24 hours, so it needs to be taken only once a day. It has been shown to be effective in the treatment of channelopathies such as long QT syndrome or catecholaminergic polymorphic VT (88,89).

Atenolol is a selective beta-1 antagonist. Because of its metabolism, it should be given 2 times per day in the pediatric population. It has been used in SVT, primary atrial tachycardias, and VTs, especially those exacerbated by catecholamines or exercise.

Although carvedilol is used more frequently in patients with heart failure, it has antiarrhythmic effects, particularly at high doses. It decreases ventricular ectopy in patients with dilated cardiomyopathy (90). Carvedilol likely has antiarrhythmic effects in addition to its beta-blocking properties—including alpha-adrenergic blocking effects and KCNH2 (HERG)-related potassium channel-blocking effects (shown in *in vitro* studies)—and has additional minimal blocking effects on sodium and calcium channels (91).

Esmolol, a short-acting selective beta-1 antagonist, is an excellent antiarrhythmic medication that can be delivered rapidly to the patient because its only form is intravenous. It has rapid clearance by erythrocyte esterases and has a half-life of 9 minutes in adults and 2 to 4 minutes in younger patients. The typical dose is 500 micrograms (mcg)/kg taken intravenously over 1 minute followed by a constant infusion at 25 mcg/kg/min. The infusion may be titrated upward until the desired effect is achieved, with a maximum of 200 mcg/kg/min. Side effects include decreased heart rate, decreased blood pressure, and, subsequently, a decreased cardiac index. Cardiac function typically recovers within 10 to 15 minutes of discontinuing the infusion.

Caution must be exercised when using beta-blockers in patients with reactive airway disease. In addition, mood changes including depression or aggression, constipation, fatigue as well as hypoglycemia can occur in children receiving beta-blockers.

Class III

Class III drugs inhibit potassium channels, which delays repolarization and prolongs the action potential.

Amiodarone is an antiarrhythmic agent with a complex array of actions, including sodium-channel inhibition, beta blockade, alpha-receptor blockade, and calcium channel-blocking activity. ECG changes can include prolongation of the PR interval, prolongation of the QT interval, a decrease in T wave amplitude, widening of the T wave, and a decrease in heart rate. It is one of the most potent antiarrhythmics, but also has the one of the most extensive side effect profiles. Amiodarone is poorly absorbed orally, with only 30% to 50% absorbed from the gastrointestinal tract, which may cause erratic bioavailability. It is highly lipophilic and distributes into many tissues. It may have a large volume of distribution (as high as 500 L), which can result in delayed onset of antiarrhythmic actions and delayed onset of side effects. The half-life ranges from 8 to 107 days. There is a poor correlation between plasma levels and efficacy, so measuring levels generally is not recommended. It is cleared by excretion in tears, sweat, and bile.

Toxicities are the primary limitation of using amiodarone and occur in up to 30% of pediatric patients (92). Many adverse reactions are related to the total cumulative dose. Photosensitivity is one of the most common side effects and is significant in up to 20% of patients. This sensitivity ranges

from susceptibility to sunburn to blue-gray discoloration of sun-exposed skin. Thyroid dysfunction is also a prominent adverse event in children. Amiodarone reduces peripheral conversion of T4 to T3, resulting in hypothyroidism (up to 10%) or hyperthyroidism. Other side effects include elevation of hepatic enzymes, weakness, peripheral neuropathy, corneal microdeposits resulting in decreased night vision, and esophageal reflux from paralysis of the lower esophageal sphincter. The most serious adverse reaction is pulmonary fibrosis, which is the only side effect that is not greatly improved or resolved by termination of amiodarone therapy (93). Fortunately, pulmonary fibrosis is extremely rare in children. Nausea is common with initiation but usually resolves with time. Amiodarone also can be given intravenously, but hypotension can occur with rapid intravenous loading, possibly because of the calcium-channel effects. Amiodarone typically does not have a significant effect on ventricular function, including in pediatric patients who have undergone recent cardiac surgery (94). It may be particularly useful in postoperative JET, which often is refractory to therapy (94). Loading should be initiated in the hospital to monitor for proarrhythmia and side effects.

In general, thyroid function tests and liver function tests should be performed at the start of therapy as a baseline and every 6 months while on amiodarone. Yearly ophthalmology examinations and pulmonary function tests (in patients able to comply, with particular attention paid to the carbon monoxide diffusing capacity) should be done to monitor for toxicity. Careful monitoring of digoxin, warfarin, and phenytoin levels should be performed because amiodarone increases levels of all these medications. Amiodarone-associated thyroid dysfunction is common in adults with congenital heart disease, with women and those with complex cyanotic lesions being at particular risk (95). In addition, amiodarone plus a beta-blocker may be effective for preventing shocks after an ICD implant (96).

Sotalol, another class III agent, initially was developed as a beta-blocker but also has the effect of prolonging the action potential as well as prolonging refractoriness. This results in prolongation of the QT interval. The drug's primary use is in SVT, but it is effective in VTs. It is well absorbed orally and is renally excreted with a half-life of 7 to 18 hours. Sotalol dosing is based on a nomogram and typically is dosed based on body surface area (60 to 200 mg/m²/day). The side effects are predominantly due to beta-blocking effects and include fatigue, dizziness, depression, headache, exacerbation of bronchospasm, bradycardia, AV block, and depression of cardiac function. Proarrhythmia can occur, with torsades de pointes being the most common, resulting from prolongation of the QT interval. The QT interval must be followed closely while patients are taking the drug because a corrected QTc <500 milliseconds has <2% risk of torsades, while a corrected QTc >550 milliseconds has a risk of torsades as high as 11%. Sotalol should be avoided in patients with hypokalemia or hypomagnesemia. Because of the incidence of symptomatic sinus bradycardia, AV block, and ventricular arrhythmias sotalol typically is initiated in the hospital with constant ECG monitoring (97).

Newer antiarrhythmic agents such as dofetilide and dronedarone may have utility in the treatment of arrhythmias in congenital heart disease patients, but there is limited experience with their use in children. Dofetilide, a class III antiarrhythmic agent, selectively inhibits the rapid component of the delayed rectifier potassium current, thus prolonging refractory periods (98). Dofetilide has been shown to be effective at controlling atrial arrhythmias in adult patients with congenital heart disease, but has a 15% incidence of excessive QT prolongation or torsades. Several patients in one study discontinued therapy because of waning effectiveness,

manifest by recurrence of their arrhythmias (99). Dronedarone is similar to amiodarone, although less potent, but has a better safety profile, lacking the thyroid, pulmonary, dermatologic, and neurologic toxicity (100). The efficacy and safety of dronedarone in patients with congenital heart disease remain to be determined. It may cause a rise in creatinine as well as liver dysfunction. An adult trial in advanced congestive heart failure patients was terminated prematurely because of excess mortality (101).

Class IV

Calcium channel blockers are Class IV agents in the Vaughn-Williams classification. Calcium channel blockers may be useful in AV node reentry tachycardia, idiopathic left VT, or right ventricular outflow tract tachycardia and to slow the ventricular response in atrial flutter or fibrillation. These drugs are relatively contraindicated in children younger than 1 year of age because of their greater sensitivity to negative inotropic effects, which may result in cardiovascular collapse and sudden death. They also are contraindicated in patients with WPW, as they may preferentially direct conduction down the accessory pathway, making ventricular fibrillation more likely.

Class V

Digoxin is classified as a Class V agent. It binds to Na-K-ATPase transport enzyme, which increases intracellular calcium via the Na-Ca exchange system. This results in an increase in vagal tone, which mediates EP effects, for instance, slowing AV node conduction and prolonging refractoriness. Applications for digoxin include controlling ventricular rate in primary atrial tachycardias and SVTs, particularly in fetal arrhythmias. Its effectiveness during exercise is limited because of low vagal tone; digoxin does not appear to blunt the heart rate during exercise. Caution should be used when giving digoxin to patients with WPW because it decreases the effective refractory period of the accessory pathway and may facilitate rapid conduction during atrial fibrillation. The half-life is age dependent: premature neonates, 60 hours; term neonates, 35 hours; infants, 18 hours; children, 37 hours; and adults, 35 to 48 hours. Adverse effects include nausea, vomiting, anorexia, headache, lethargy, confusion, and visual changes. Cardiac adverse effects include sinus bradycardia, AV block, supraventricular ectopy, ventricular ectopy, VT, and ventricular fibrillation. Digoxin may increase the risk of refractory ventricular arrhythmias or bradyarrhythmias after DC cardioversion. It is excreted primarily by the kidneys and must be used with extreme caution in patients with renal failure or the potential to develop renal dysfunction. Predisposing factors to toxicity also include increased myocardial sensitivity due to hypokalemia, hypomagnesemia, hypocalcemia, myocardial ischemia, myocarditis, and hypoxemia or taking drugs that decrease digoxin clearance, such as amiodarone, verapamil, spironolactone, or erythromycin.

Digitalis toxicity may present as a prolonged PR interval, ST segment changes, AV block, or ectopic junctional, atrial, or ventricular arrhythmias. Toxicity treatment may include atropine for bradycardia and AV block and lidocaine and/or phenytoin (class Ib antiarrhythmic) for tachycardias. High levels may require digoxin-immune Fab antibody therapy.

Adenosine

Adenosine works on specific receptors that are linked to potassium-channel stimulation located in the sinus and AV nodes.

TABLE 18.4 Pharmacologic Treatment of Arrhythmias

Treatment of Automaticity (AET)
Decrease phase 4 and 0 depolarization
β -Blocker (propranolol)
Sodium channel blocker (flecainide)
Alter surrounding tissue
Slow conduction ($\downarrow V_{max}$)
Na ⁺ channel blocker (flecainide)
Prolong refractoriness (TERP)
Class III agent (sotalol, amiodarone)
Treatment of reentry
Decrease conductivity of one limb
Na ⁺ -channel blockers (procainamide, flecainide)
β -Blockers (propranolol, atenolol)
Prolong refractoriness of one limb
Class Ia Agents (procainamide)
Class III Agents (sotalol, amiodarone)
Frequently, AVN is one limb of circuit
Calcium channel blockers (except in WPW)
β -Blockers
Treatment of triggered activity
Shorten action potential duration
Class Ib (mexiletine)
Suppress Afterdepolarizations
β -blockers (propranolol, atenolol, nadolol)

Activation of these receptors shortens the action potential duration. The EP effects include decreased rate of sinus node firing, slowing or block of AV nodal conduction, and shortening of atrial action potential. There is a biphasic response in the sinus node with an initial bradycardia that is a direct effect of activation of adenosine receptors followed by a subsequent sinus tachycardia that is an indirect effect from an autonomic reflex from carotid body chemoreceptors. Adenosine is metabolized rapidly by erythrocytes and endothelial tissue with a very short half-life of 1 to 5 seconds. The dose is usually 100 to 200 $\mu\text{g}/\text{kg}$, with a maximum dose of 12 mg, but doses of up to 400 $\mu\text{g}/\text{kg}$ may be given in refractory cases. Adenosine can be used in both the acute management of SVT to terminate reentrant arrhythmias and to establish the diagnosis in atrial arrhythmias. If the tachycardia is dependent on the AV node (AV node reentry tachycardia or accessory pathway-mediated tachycardia), it typically will terminate with adenosine. Atrial flutter or IART typically will not be affected by adenosine, but blocking the AV node and thus the ventricular response may reveal tachycardia that is masked by the QRS complex or T wave. Generally, automatic focus tachycardias (atrial or ventricular) are not affected but occasionally will terminate with adenosine administration. For this reason, an ECG recording during adenosine administration is very important. Adverse effects include chest discomfort, flushing, acute bronchospasm, and hypotension. The delayed chemoreceptor reflex may accelerate AV nodal conduction of atrial arrhythmias or precipitate atrial fibrillation. The initial bradycardia may precipitate torsades in patients with congenital or drug-induced prolonged QT. Patients who have had heart transplantation may be particularly sensitive to adenosine, resulting in long periods of ventricular asystole. A dose

of one-quarter to one-half the typical dose should be used in these patients.

In cases where adenosine is unsuccessful, it is important to determine the specific circumstances. If the adenosine is not given fast enough, there may be no response whatsoever. Other tachycardias (like sinus tachycardia) may temporarily slow down, but then immediately resume when the adenosine has been metabolized. Reentrant tachycardias using an accessory pathway may terminate, but then be reinitiated by a premature beat immediately after termination. Junctional or VTs may show temporary ventriculoatrial (VA) block with resultant VA dissociation without affecting the underlying tachycardia. As there are multiple reasons why adenosine “didn’t work,” it is important to obtain an ECG or rhythm strip during adenosine administration to determine the true response.

Magnesium

Magnesium also can be used as an antiarrhythmic agent, but its mechanism of action is not well established. Magnesium slows conduction in the AV node and suppresses after depolarizations. It should be considered as a first-line agent in patients with torsades de pointes, particularly those caused by congenital or drug-acquired long QT syndrome, and may have use in digitalis toxicity (102,103).

OTHER THERAPIES

In the case of reentrant tachycardias, pacing faster than the tachycardia cycle length can disrupt the circuit and terminate the tachycardia. This is particularly useful in the postoperative setting, where atrial and ventricular temporary pacing wires provide a means to pace the heart, or in the presence of implantable pacemakers or defibrillators. Alternatively, catheters can be placed transesophageally (for atrial flutter or reentrant SVT) or transvenously to pace terminate tachycardias. For patients presenting with intractable arrhythmias associated with poor ventricular function or myocarditis, mechanical support is an option until the tachycardia can be eliminated or controlled (104).

Defibrillation/Cardioversion

Defibrillation is the electrical conversion of a disorganized ventricular fibrillation into a normal rhythm. Cardioversion is the conversion of an organized tachycardia. For an organized tachycardia with a pulse, the energy should be delivered using a shock synchronized to the QRS complex. For ventricular fibrillation or torsades, an unsynchronized shock should be used. If the defibrillator is not able to sense QRS complexes, it will NOT discharge in the “synchronized” mode.

Defibrillation may be performed using either standard paddles or adhesive patches. Patches have the advantage of not requiring an operator to hold the paddles in position. For ventricular conversion, patches may be placed in the standard position of one patch to the right of the sternum and the other at the ventricular apex in the mid axillary line. For atrial tachycardias, it is beneficial to place the patches directly on the front and back of the chest. For unsuccessful cardioversions, it is important to differentiate from an unsuccessful defibrillation due to inadequate energy dose or improper paddle placement from termination with immediate reinitiation of the arrhythmia.

It is critically important to begin cardiopulmonary resuscitation (CPR) as soon as an arrest starts and defibrillate the heart as quickly as possible after an arrest. Even if there is an organized electrical activity on the ECG, one should always check a pulse to ensure that the electrical activity is creating a mechanical contraction. If no pulse is palpable, CPR should be resumed. It also is important to give sedation to awake patients as the energy delivered is a painful stimulus.

Antiarrhythmic medications may have an effect on defibrillation threshold from external defibrillators as well as ICDs. An increase in defibrillation thresholds is seen with flecainide, propafenone, amiodarone, and lidocaine, while sotalol and beta-blockers decrease defibrillation thresholds (105).

BRADYCARDIA

Bradycardias are defined as a heart rate less than normal for age. The most important distinction in bradycardias is differentiation of transient, functional slowing of the heart rate from that caused by an underlying disease of the conduction system.

Sinus Bradycardia

A hallmark feature of the sinus node is its adaptability to change. The majority of these changes are physiologic resulting from physical activity, fever, sleep, or illness. The autonomic nervous system plays a vital role in regulating the depolarizations and, therefore, the rate of sinoatrial nodal cell discharges. While the normal sinus rate for an adult is between 50 and 90 beats per minute, these rates vary in pediatrics based on age (see Table 18.1).

The definition of sinus bradycardia is a rhythm that originates in the sinoatrial node and is less than the lower rate acceptable for age (see Fig. 18.21). In addition, the axis of the P wave should be between 0 and 90 degrees (an upright P wave in leads I and aVF on the ECG), with each P resulting in normal AV activation. As previously stated, the sinus node may extend inferiorly to near the orifice of the inferior vena cava, therefore occasionally resulting in a slight shift in this P wave axis with a focus in the low right atrium resulting in a negative P wave in lead aVF on the ECG, but this is only seen at slower heart rates and typically reverts to the normal location at higher rates. Absolute limits for sinus bradycardia with a pediatric population have not been established firmly

because most of the studies performed in this area have not evaluated “normal” children (i.e., those without an indication for either an ECG or Holter monitor).

Sinus bradycardia is, in general, a benign entity that often occurs in athletes or during rest/sleep. Each person has his or her own set heart rate, and rates below “normal” values may be seen but may be completely normal and physiologically appropriate for an otherwise asymptomatic individual. Because of the general lack of symptoms, the true incidence of sinus bradycardia in the pediatric population is unknown. In a study performed on highly trained junior athletes, many subjects were found to have marked sinus bradycardia (106). Although the majority of patients with sinus bradycardia are asymptomatic, some may have symptoms of fatigue, syncope, exercise intolerance, sleepiness, and/or nightmares (107).

Common causes of sinus bradycardia include physical conditioning, anorexia, medications, or acute infections. Periods of abrupt sinus bradycardia and/or sinus arrest can occur in breath-holding spells or vasovagal/autonomic-mediated syncope. After a diagnosis of sinus bradycardia, a thorough history and review of symptoms is warranted to attempt to rule out a pathologic cause. Reversible causes of sinus bradycardia include such disorders as Cushing’s triad (acute increase in intracranial pressure, hypertension, and irregular respiration), hyperkalemia, hypercalcemia, hypoxia, hypothyroidism, hypothermia, and ingestions of such substances as beta-blockers, lithium, and digitalis (108). Rarely, cases of sinus bradycardia also may signify another disease such as myocarditis, diphtheria, or rheumatic fever (109).

The initial evaluation for a patient with bradycardia involves a complete history, physical examination, and an ECG. Having the patient do mild exercise (jumping jacks) in the office and then repeating an ECG may be sufficient evidence of normal sinus node functioning. If additional testing is necessary to confirm sinus bradycardia, other noninvasive tests such as a Holter monitor, an event monitor, or a 30-day loop recorder may be indicated. These tests have the advantage over the ECG in that the patient’s symptoms can be logged and directly correlated with symptoms. If these tests are not helpful or worry persists, the exercise stress test is another noninvasive test that can help rule out a pathologic sinus bradycardia. Invasive testing of the sinus node (sinus node recovery times or SNRTs) essentially has been abandoned in pediatrics because of its lack of sensitivity and specificity along with the ease of Holter monitoring and exercise stress testing.

The exercise stress test can be performed on children as young as 4 to 5 years old. This test is designed to give precise

Figure 18.21. Sinus bradycardia in a newborn. Note the slow rate with a normal P wave axis in an otherwise normal ECG. The pauses between two beats may be representative of underlying SND.

measurements of heart rate in response to an increasing load. The goal of exercise testing in a child with sinus bradycardia is to determine their maximal heart rate response. The diagnosis of SND—defined as any disturbance, impairment, or abnormality in the function of the sinus node—depends on the patient's effort, as the normal peak heart rate achievable during exercise stress testing is dependent on patient age and effort. The vast majority of patients who have an exercise test as an evaluation for sinus bradycardia achieves normal peak heart rates and therefore needs no further workup. Those patients who achieve a normal peak heart rate that is significantly lower than expected (typically <135 beats per minute) or have an exaggerated, rapid decline in heart rate during recovery may have SND rather than simple sinus bradycardia.

Treatment

The only reason to treat patients with sinus bradycardia is when symptoms of fatigue or syncope are temporally correlated with the presence of a slow heart rate on multiple occasions. Routine sinus bradycardia in the absence of any underlying cause or symptoms does not require treatment. Severe cases of autonomic dysfunction or breath-holding spells with frequent sinus pauses resulting in syncope may benefit from pacemaker placement, but this almost never is necessary, particularly in young children for whom the symptoms frequently will resolve by age 4 to 6. In addition, there is frequently a blood pressure drop in older patients that may result in continued symptoms and syncope despite an adequate heart rate.

Sinus Node Dysfunction

SND generally occurs in the setting of sinus bradycardia with slow escape rhythms and can be associated with tachyarrhythmias such as atrial fibrillation or flutter. This disorder is somewhat uncommon in the pediatric age group but becomes more prevalent in adults who had congenital heart surgery at earlier ages. There are two main groups of SND in the pediatric age group. In the first, disease is caused by a primary disorder associated with ion channels in the sinus node (a channelopathy). This is discussed in another chapter (see Chapter 16). Disease in the second group has causes such as vagal tone, congenital heart disease, postsurgical state, or a reversible cause including hypothyroidism or medications.

Most patients with SND, like those with sinus bradycardia, are asymptomatic. Multiple factors may be directly attributed to the fact that these patients, in spite of slow or absent sinus rhythm, are asymptomatic. First and foremost is that the presence of symptoms depends on the function of the remaining cardiac conduction system (atrium, AV node, and ventricles). If the patient has an appropriate atrial or junctional escape rhythm, they may be completely asymptomatic. Their clinical presentation also depends, in large part, upon age, with older patients tending to be asymptomatic, in part because they tend to self-limit and therefore symptoms such as exercise intolerance and fatigue go unnoticed. Infants with SND tend to present with poor feeding, lethargy, and failure to thrive while older children and adults are relatively asymptomatic. In studies performed on children with SND, almost 75% were asymptomatic (107,110). Those who experience symptoms may have only subtle signs of fatigue, inability to keep up with their peers, shortness of breath, syncope, or more marked symptoms of congestive heart failure or IART. Sudden death also has been reported in rare patients with SND, but these cases tend to involve primary SND and, contrary to popular belief, not secondary SND (111–113).

Etiology of sinus node dysfunction

There is a myriad of causes of SND in the pediatric age group, including ion channelopathies, malignancies, inflammatory disorders, cardiomyopathies, structural heart disease, and surgical damage. In addition, readily reversible causes include hypothyroidism, increased vagal tone, hypothermia, and medications. For this section, the focus is on the surgical and untreatable causes.

SND may result from cardiac surgery and disruption of the sinus node artery during the repair or during placement of the superior vena cava cannula for cardiopulmonary bypass (114a,114b,115). For a complete list of nonreversible, nongenetic causes of SND, please refer to Table 18.5.

The evaluation of SND is the same as for patients with sinus bradycardia. One clue that may help differentiate SND from sinus bradycardia is the complete absence of sinus node activity with slow escape rates or atrial flutter or fibrillation following a sinus pause as these are not typically seen in patients with a normal sinus node. If clinically indicated, laboratory evaluation including a drug screen, thyroid function tests and evaluation for rheumatic disorders, infections, or metabolic causes may be performed.

Treatment

When a reversible cause of SND has been excluded and symptomatic SND is present, the treatment is implantation of a permanent pacemaker. This includes patients with chronotropic incompetence as a result of required drug therapy.

Disorders of Atrioventricular Conduction

The term AV block describes an abnormality in the conduction of atrial impulses through the AV node to the ventricles.

TABLE 18.5

Nonreversible, Nongenetic Causes of SND

Congenital Heart Disease

Atrial septal defects, primum, secundum, and sinus venosus

Pulmonary stenosis

Ventricular septal defects

Transposition of the great arteries

Single ventricle

Patent ductus arteriosus

Coarctation of aorta

WPW syndrome

Cardiomyopathies

Idiopathic, hypertrophic, and infiltrative

Inflammatory

Muscular dystrophy, of all types, especially Emery-Dreifuss

Friedreich ataxia

Kawasaki disease

Other

Tumor

Guillain-Barré

Kearns-Sayre syndrome

This abnormality can range from a simple delay in impulse transmission, as in first-degree AV block, to a complete interruption of signal transmission, classified as complete, or third-degree, AV block. Each form of AV block has a distinct anatomic or physiologic cause for the electrical abnormality and can be either transient or permanent in nature. The cause of this arrhythmia may be structural cardiac disease, trauma, myocardial infarction or inflammation, or abnormal impulse propagation from an underlying cardiac channelopathy. In pediatric patients, the majority of block occurs in the AV node proper (116). The block can result from enhanced vagal tone, congenital heart disease, surgery, or infections such as Lyme disease (117).

First-Degree Atrioventricular Block

First-degree AV block is defined as prolonged conduction through the AV node that is greater than accepted for age (see Fig. 18.22). Although called “AV block,” it is not truly a block and a more correct terminology may be “prolonged PR interval.” The upper limit for the PR interval, like other ECG findings in pediatrics, varies with age, ranging from 70 milliseconds in infants to 200 milliseconds in adolescents. It manifests as prolongation of the PR interval with every P wave followed by a QRS complex. It can be caused by delay within the atrium, AV node, or His-Purkinje system. Generally, the finding is normal, with a prevalence of up to 8% of normal children (118). This ECG finding also has been described in patients with a patent ductus arteriosus (119). Other causes of first-degree AV block include increased vagal tone, acute rheumatic fever, Ebstein’s anomaly, medications (digoxin, calcium channel blockers, sotalol, amiodarone, and procainamide), and electrolyte disturbances (hyper- and hypokalemia and -calcemia as well as hypomagnesemia). Despite the severity of disorders and medications, this ECG finding has little clinical significance and generally requires no treatment. In some children, there is no underlying cause, and it may be considered normal for that individual.

Second-Degree Atrioventricular Block

Second-degree AV block is defined as the failure of at least one nonpremature atrial impulse to conduct to the ventricles. A number of different forms of second-degree AV block exist (see Fig. 18.23). These include Mobitz type I, Mobitz type II, 2:1 AV block, and high-grade second-degree AV

block (presence of some AV conduction, but more than two consecutive P waves fail to conduct).

Mobitz type I, or Wenckebach, is the most common type of second-degree AV block. Typical Wenckebach is characterized by the following four criteria (120):

1. Progressive prolongation of the PR intervals
2. PR interval prolongation at progressively decreasing increments
3. Progressive shortening of the RR interval
4. Eventual failure to conduct an atrial beat to the ventricle

When Wenckebach occurs with a normal QRS duration, the location of the delay is in the AV node, proximal to the bundle of His (120). When the QRS duration is prolonged and Wenckebach occurs, the block may be in the AV node or within and/or below the His bundle.

This conduction abnormality most commonly is transient in nature and caused by vagal influence. The majority of episodes of Wenckebach occurs in healthy, asymptomatic patients during sleep or other times of high resting vagal tone. A small percentage of patients may have underlying AV node disease or a progressive conduction system disturbance. Wenckebach typically does not occur while awake except rarely in highly trained professional athletes. Wenckebach during exercise or at times of increased catecholamine state is pathologic and should be thoroughly evaluated for the presence of conduction system disease. If the Wenckebach is thought to be physiologic (particularly during sleep), no therapy is required and follow-up is unnecessary.

The pathologic form of second-degree AV block, or Mobitz type II, is characterized by a constant P-P interval without lengthening of the PR interval prior to the nonconducted P. This rare conduction abnormality generally but not always represents a conduction defect below the bundle of His (121). The most common reason for this problem in the pediatric population is myocarditis and/or postsurgical complications. Another potentially lethal cause has been described in patients who develop rejection after cardiac transplant (122,123) or who have posttransplant coronary artery disease (124). If a reversible cause for this form of AV block cannot be found, the recommendation is for implantation of a permanent pacemaker.

Another form of AV block that rarely occurs in pediatric patients is 2:1 AV block. This arrhythmia generally occurs in a patient during times of high vagal tone such as sleep but also may be seen in patients with long QT syndrome. It is impossible to classify 2:1 AV block as either type I or II because there

Figure 18.22. First-degree AV block. Note the prolonged PR interval with otherwise normal conduction in a 1:1 manner from the atrium to the ventricle. This finding is typically benign and related to an increased vagal tone or resting state. At faster heart rates, it may be a marker of atrial tachycardia or AV nodal conduction disease.

Figure 18.23. Second-degree AV block. A: Mobitz type I or Wenckebach with progressive prolongation of the PR interval followed by a dropped beat. This finding may be normal, particularly during sleep. B: Mobitz type II with no prolongation of the PR interval prior to a dropped beat. This type of block is always pathologic.

is no stable PR interval with successively conducted beats. The presence of Mobitz type I or Mobitz type II block on a long rhythm strip or 24-hour monitor may help to distinguish these two types. Differentiation also can be performed using an intracardiac tracing by looking for the presence of a bundle of His recording following the atrial depolarization. If the His is present, block occurs below the AV node. In addition, most patients who have Mobitz type II block have an underlying bundle branch block, although patients with Mobitz type I may as well. The treatment for 2:1 AV block is no different from that already outlined for type I and II AV block. The QT interval should be carefully measured in patients with 2:1 AV block as long QT syndrome can result in this finding.

High-grade or advanced second-degree AV block occurs when there are two or more successive sinoatrial impulses that are not propagated through the AV node. This form of AV block may have a reversible cause, such as acute myocarditis and rheumatic fever, an irreversible cause such as lupus or congenital cardiac disorders, or as a direct result of cardiac surgery (125–128). Patients with this conduction disorder need to be evaluated at regular intervals. The majority of these patients, regardless of symptoms, will require pacemaker implantation. In the asymptomatic patient with an unknown

cause of advanced second-degree AV block and a structurally normal heart, management would be similar to that of complete AV block (CAVB).

Complete Atrioventricular Block

CAVB, or third-degree AV block, is the complete failure of sinus atrial impulse conduction to the ventricles (Fig. 18.24). In addition, the atrial rate must be faster than the ventricular rate to assure that the AV dissociation is not caused by a junctional or ventricular rhythm (e.g., sinus bradycardia with junctional escape or an accelerated junctional or ventricular rhythm). This rhythm disturbance generally is diagnosed using an ECG and confirmed by a 24-hour Holter monitor. There is currently no indication for EP testing in patients with CAVB.

The incidence of congenital CAVB (CCAVB) in live-born infants is 1 in 20,000 (129). The majority of affected pediatric patients come from three distinct groups: those with structural cardiac disease, maternal connective tissue disorders, or cardiovascular surgery complications (130–132). In addition, other causes of CAVB have been described including infections, myopathies, and genetic disorders (133–135).

Figure 18.24. Complete AV block. The atrial rate is faster than the ventricular rate, there is no relationship between the P waves and the QRS complexes, and there are P waves that should conduct but do not.

The first major cause of CAVB is associated with structural cardiac disorders. The etiology of nonimmune CAVB has been postulated by Lev (136) to occur as the result of a developmental abnormality of the AV node. This can be caused by a complete absence of the AV node, lack of union between the AV node and distal conduction system, or the presence of an aberrant, nonfunctioning, or poorly functioning system. The most common structural cardiac abnormalities associated with CAVB are AV septal defects, both with and without associated left atrial isomerism and AV discordance with ventriculoarterial discordance (congenitally corrected transposition of the great arteries) (130,132). Additional cardiovascular malformations (tetralogy of Fallot, atrial septal defects, transposition of the great vessels, and tricuspid atresia) have been described, without any apparent association between the structural abnormality and the conduction defect (130,132).

A second major cause of CAVB can be attributed to maternal autoimmune disorders (137,138). It occurs in fetuses of mothers with systemic lupus erythematosus (SLE), Sjogren syndrome, rheumatoid arthritis, scleroderma, and undifferentiated connective tissue disorders (139–141). Specifically, it has been associated strongly with maternal autoantibodies designated as anti-SS-A/Ro, anti-SS-B/La, or both (142). Many women who deliver babies with CAVB do not have symptoms of any connective tissue disorder at the time, with half demonstrating only serologic evidence of their disease (143). In addition, the vast majority of mothers with SLE will not have offspring with CAVB. Their risk of conceiving an infant with CAVB is only 1 in 60 (144). If maternal autoantibodies to SSA/Ro are present, that risk, 1 in 20, increases dramatically (145). The risk of recurrence of CAVB in subsequent pregnancies is between 10% and 16% (142).

The mechanism of damage to the conduction system occurs when maternal antibodies cross the placenta and react with their corresponding antigens expressed on the surface of cells of the fetal cardiac conduction system, resulting in immunoglobulin deposition on the cells of the fetal conduction system and on the cardiac myocytes. This local inflammatory reaction leads to permanent damage to the fetal cardiac conduction system because of localized cellular apoptosis (146–150). Patients with antinuclear antibodies may have a higher incidence of long-term development of heart failure and death compared to those who are antibody negative (151).

The third major cause of CAVB is as a direct result of a surgical or catheter intervention that results in damage to the His bundle or AV node. In a number of surgical repairs, damage to the AV node is a known complication because of the close proximity between the defect and the conduction system. These defects include perimembranous ventricular septal defects, AV canal repairs, and congenitally corrected transposition of the great arteries with ventricular septal defect. In other repairs, such as aortic and mitral valve replacements, the prosthetic valve tissue often impinges on the normal AV conduction system, which also results in block.

AV block remains a relatively rare complication of cardiovascular surgery, affecting overall fewer than 3% of patients. A number of preoperative and intraoperative risks have been identified in these patients, including younger age, lower weights, and longer aortic cross clamp or cardiopulmonary bypass (84). Often this type of block is temporary and does not require long-term treatment although patients can be at an increased long-term risk for developing AV block. In this era of cardiovascular surgery, the majority of surgeons place temporary pacing wires at the time of repair that can be removed 2 to 3 days following surgery if no signs of conduction block have occurred (152). If any conduction block is noted, the heart can be paced until it is determined that normal conduction has returned or the patient requires a more permanent system.

Since the advent of catheter interventions for the treatment of arrhythmias or to occlude septal defects, an additional cause of AV block has emerged. EP procedures and a number of percutaneous catheter interventions also pose a risk of developing AV block either as an acute or late complication. The risk of AV block in these patients is thought to be as a direct result of impingement of the device (septal occluder or aortic or pulmonary valve) on the AV node (153–156). In the majority of patients, the AV block is noted acutely and can be rectified by device removal. However, some patients develop this as a late complication. These tend to be permanent.

In addition to these well-known causes, a small group of patients has been identified with a genetic mutation that results in CAVB. A mutation in the cardiac transcription factor NKX2.5 can result in familial atrial septal defects or hypoplastic left heart syndrome in an autosomal dominant inheritance pattern (157). AV node conduction abnormalities also occur in Holt-Oram syndrome and atrial septal defects. Patients with structurally normal hearts and a mutation in SCN5A, a sodium ion channel responsible for long QT and Brugada syndrome, can have a range of AV conduction abnormalities, including complete block (158). In addition, infections may produce AV block including acute rheumatic fever, Chagas disease, diphtheria, and Rocky Mountain spotted fever. Lyme disease also can present with high-grade AV block, which may be the only manifestation of this infection.

Symptoms and Treatment

Fetal Congenital Complete Atrioventricular Block

A wide range of symptoms has been identified in patients with CAVB. The symptoms that patients present with tend to depend, at least in part, on the patient's age at presentation. CCAVB, when identified in a fetus, can vary from asymptomatic to hydrops fetalis. Recent studies have documented exceptionally high mortality rates for these patients, ranging from 7% to 33% in infants and fetuses with structurally normal hearts and as high as 86% in those with structural cardiac lesions (130–132,143,159). Poor outcomes are associated with the presence of structural cardiac disease, hydrops, ventricular rates <55 beats per minute, AV valve regurgitation, dilated cardiomyopathy, prolonged corrected QT interval, or delivery at or before 32 weeks' gestation (130–132,143,159).

The goal of managing a fetus with CAVB is the birth of a healthy infant. This outcome can best be accomplished by early intervention at the first sign of the problems listed in the prior paragraph. Also, identification of fetuses at risk for developing CAVB is important, allowing the initiation of therapies to prevent the onset or progression of the conduction abnormality. These goals can be accomplished by increasing the fetal heart rate and/or contractility or by removing the inflammatory agents or modulating it through immune suppression.

The maternal or direct fetal administration of sympathomimetic agents such as ritodrine, terbutaline, isoproterenol, and salbutamol may improve both fetal heart rates and contractility (130,160–162). These medications are not given routinely as there frequently is no improvement because AV conduction has not been restored. However, it has been proposed that a trial of sympathomimetics should be considered in fetuses with CAVB with signs of deterioration (160). The reduction of the maternal antibody titer through plasmapheresis also has been performed but with variable results. Also, the use of intravenous gamma globulin has resulted in a complete reduction of the maternal anti-Ro antibody titer (163). Only a limited number of patients has had these therapies during pregnancy and they are not used in most centers.

The use of fluorinated steroids, dexamethasone and betamethasone for the treatment and prevention of CAVB also has been reported (130,131,142,164–166). In one study comparing the use of fluorinated steroids to an untreated control group, the use of steroids in fetuses that already had developed CAVB failed to restore any AV conduction but somewhat improved hydrops and other symptoms (167). Steroids administered soon after the onset of second-degree AV block may result in the permanent reversal of advanced AV conduction disorders in some fetuses, and fluorinated steroids should be considered in fetuses with early forms of AV block and/or hydrops.

In summary, fetal CAVB is a relatively rare condition with evolving management. It is recommended that all mothers with anti Ro and La antibodies (SSA and SSB) have an early fetal echocardiogram. In the fetus of a mother with a connective tissue disorder, early detection of advanced AV conduction abnormalities and/or hydrops should prompt the consideration to use fluorinated steroids with the goal of preventing the progression of the inflammatory process. In addition, referral to a center with expertise in high-risk obstetrics, fetal cardiology, and pediatric and neonatal pacemaker implantation and management should be considered strongly near the time of delivery.

CAVB in Infants, Children, and Young Adults

A wide array of symptoms occurs in infants, children, and young adults with structurally normal hearts and CAVB. These symptoms range from nothing to Stokes-Adams attacks (sudden transient episode of syncope) and sudden cardiac death. The underlying reason for symptoms or lack of symptoms is the patient's underlying escape rate and rhythm. Those patients with a reasonable junctional escape that is chronotropically competent tend to be relatively asymptomatic. Those with very slow resting heart rates that do not significantly increase with exercise tend to have symptoms of fatigue, syncope, nightmares, or even congestive heart failure.

After documentation of CCAVB in asymptomatic patients with an ECG, their evaluation includes a number of tests to determine whether they meet criteria for implantation of a pacing system. In patients newly diagnosed with CCAVB, an echocardiogram routinely is performed to evaluate for structural cardiac disease or myocarditis. If a congenital cardiac anomaly is a hemodynamically significant defect, then a pacing system is recommended if there are symptoms or if the heart rate is <70 regardless of symptoms. This recommendation stems from an increased incidence of death (29% vs. 8%) in patients with structural heart disease when compared to normal patients (168).

In asymptomatic patients with structurally normal hearts, the first test is a 24-hour Holter monitor to detect episodes of abrupt pauses >2 to 3 times the underlying cycle length, average heart rate <50 beats per minute, complex ventricular ectopy, wide QRS escape rhythm, VT, or symptoms associated with slow heart rates, all of which are indications for pacing. After the Holter monitor, the next test (in patients old enough to participate) is an exercise stress test. During the test, careful attention is paid to the patient's maximal heart rate at peak exercise and symptoms. If the patient has symptoms, an increase in ventricular ectopy or an episode of VT, pacing may be indicated. The final test, usually performed on an annual basis, is an echocardiogram to evaluate the size and function of the left ventricle.

CCAVB patients compensate for their reduced heart rate by increasing their left ventricular end diastolic volume and therefore their stroke volume. It is common to see ventricular dilation in these patients on echocardiography, but the function typically is normal or hyperdynamic. A decrease in function or extreme dilation is concerning and may require pacemaker implantation. In those patients with CCAVB who do not meet requirements for pacemaker implantation by their late teen

years, prophylactic pacemaker implantation may be considered. This is based on a large prospective study of adults with isolated congenital heart disease, in which the authors found that 50% of previously asymptomatic adult patients develop symptoms and 10% will die prematurely (169).

When surgical AV block is identified, these patients must be paced temporarily in the immediate postoperative phase. The underlying junctional escape rhythm in these patients is not reliable and may result in episodes of asystole. In addition, pacing allows a more appropriate ventricular rate and a restoration of AV synchrony that can be important to the patients' hemodynamic status. Paced patients with surgical AV block should be evaluated daily for return of native AV conduction. Atrial and ventricular lead capture thresholds should be adjusted to at least twice the safety margin (lowest output that reliably captures the myocardium). The patient should have implantation of a permanent pacing system if the AV block is not expected to resolve or persists at least 7 days following surgery. Without implantation of a pacing system in postoperative AV block, the mortality rate has been reported to be as high as 60% within the first year alone (170).

If temporary pacing for hemodynamically significant AV block is needed, there are several options. The first is transcutaneous pacing that can be performed through many external defibrillators. This may provide a temporary method for pacing the heart, but is not a good long-term solution and usually is not tolerable in an alert patient. Temporary pacing catheters also can be placed through the femoral or internal jugular veins to stimulate the heart. Pacing typically is performed in the ventricle regardless of the source of bradycardia to ensure an adequate ventricular rate to provide blood flow to the body. There are three types of catheters. The first uses a balloon to guide the catheter into position. This is helpful, unless there is ventricular asystole with no forward flow to guide the balloon into the ventricle. The second is a fixed curve or deflectable catheter used for EP studies that can be placed into the ventricle. In general, this requires fluoroscopic guidance in the cath lab to properly position. The final type is a temporary pacing catheter that has a small electrode tip that is actually screwed into the myocardium under fluoroscopic guidance. This technique has the advantage of having a stable position with little chance for dislodgement with subsequent loss of pacing capture, but is more difficult to place and remove. All of these are temporary solutions and require assessment for the need for a permanent pacing system after being in place for 1 to 2 days.

Bundle Branch Block

Synchronous depolarization of the left and right ventricles occurs through specialized conduction tissue and results in a narrow complex QRS on the ECG. This conduction tissue divides into a left and right bundle branch after the bundle of His. The right bundle continues into the right ventricular apex and then turns anteriorly and is contiguous with the moderator band. Typically, the left bundle branch quickly subdivides into a left anterior and left posterior fascicle resulting in activation of the left ventricle prior to the right ventricle.

When activation in one of these bundles is delayed, it results in a prolonged QRS duration for age. A right bundle branch block typically has a conduction delay in lead V1 with an initial positive deflection followed by a deflection below the baseline followed by another positive deflection (RSR' pattern). A left bundle branch will typically have this pattern in lead V6 (see Fig. 18.25).

This conduction delay may be congenital or acquired. Congenital autosomal dominant right bundle branch block is a hereditary condition that typically is associated with normal cardiac function and no long-term consequences. Congenital

Figure 18.25. Bundle branch block. **A:** Right bundle branch block with an RSR' pattern in V1 and slurred S wave in V6. **B:** Left bundle branch block with an RSR' pattern in V6 and slurred S wave in V1.

right bundle branch block also occurs frequently with Ebstein anomaly of the tricuspid valve. Right bundle branch block also can occur in ARVC, myocarditis, following orthotopic heart transplantation or in Brugada syndrome (typically right bundle branch only in lead V1 and/or V2). More commonly right bundle branch block is acquired following cardiac surgery particularly following ventricular septal defect or AV canal repair. Left bundle branch block is rare in the pediatric population. Kearns-Sayre syndrome and myotonic dystrophy can present with first or second-degree AV block that may progress to higher levels of AV block and may therefore require early pacemaker implantation.

PACEMAKERS AND IMPLANTABLE CARDIOVERTER DEFIBRILLATORS

The original description of pediatric pacemaker implantations occurred in the 1960s and involved patients who had surgical CAVB (171). Since that time, the indication for pediatric devices has expanded and the technology has advanced. Only basic concepts are discussed as there is a large number of textbooks dedicated completely to a more in-depth examination of pacing and defibrillation indications, technology, and

implantation techniques. These devices consist of a generator that contains the battery, circuitry and computer, and a lead that connects the generator to the myocardium. Leads can be placed through the venous system and placed on the endocardial surface of the heart (transvenous leads) or affixed directly on the outer surface of the heart by a surgeon (epicardial leads). Newer lead technology allows the lead to be placed on the myocardium and communicate wirelessly to the generator.

Pacemakers perform four basic functions:

- Stimulate cardiac depolarization
- Sense intrinsic cardiac function
- Respond to increased metabolic demand by providing rate-responsive pacing
- Provide diagnostic information stored by the pacemaker

An ICD performs all of the above functions but is able to detect VT and deliver antitachycardia pacing or a shock through the device to attempt to cardiovert or defibrillate the patient. The North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group Generic (NBG) code was created as a standard method of describing the mode of pacing, the mode of sensing, and how the pacemaker will respond to the presence or absence of intrinsic beats.(172) (see Table 18.6).

TABLE 18.6 Revised NASPE/BPEG Generic Code

Position	1	2	3	4	5
Category	Chamber(s) paced	Chamber(s) Sensed	Response to sensing	Rate modulation	Multisite pacing
Letters used	0 = none A = atrial V = ventricle D = dual (A + V)	0 = none A = atrial V = ventricle D = dual (A + V)	0 = none T = triggered I = inhibit D = dual (T + I)	0 = none R = Rate modulation	0 = none A = atrial V = ventricle D = dual (A + V)

A triggered response is an active pacing response to a sensed event. This is used in dual-chamber pacemakers so that the underlying sinus rate can be "tracked" resulting in a 1:1 relationship between the atria and ventricles. An inhibit response results in the pacemaker not firing so that pacing does not occur when an intrinsic event is present. Rate modulation involves sensors in the device that increase the heart rate in response to motion to simulate the increase in heart rate seen with physical activity. Multisite pacing involves more than one pacing lead in a particular chamber to create a more synchronous contraction. (Adapted from Bernstein, et al. The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing. North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group. *Pacing Clin Electrophysiol* 2002;25:260–264.)

The indications for pacing and defibrillation for children are relatively similar to those for adult patients, but due to patient size, activity level, longevity, and venous access, a number of unique considerations make the decision to implant a device not as straightforward. What type of device (single, dual, or multichamber) and how the device is implanted (transvenous versus epicardial) are the first decisions one must make after the decision to pace has been reached. These decisions are influenced by the patient's size, the presence of unrepaired structural cardiac disease or residual shunting, the inability to access the heart through the existing venous anatomy, and the necessity of device implantation.

The overall goal of any device is to improve the patient's underlying conduction abnormality while not limiting future decisions to upgrade the system. An example might be a

7-year-old patient with SND and intact AV node function: This patient's subclavian vein may be too small for implantation of a dual-chamber pacing system, but implanting a single-chamber system capable of pacing the atrium and allowing conduction down the intact AV node is a wise compromise. These decisions also may affect the ability to pace/defibrillate the patient through transvenous systems long term. The clinician's goal is to pace the patient in a manner that will allow for continued pacing throughout the patient's lifespan.

The 2008 guidelines for device-based therapy of cardiac rhythm abnormalities are categorized into different classes and different levels within each class. The indications for the implantation of a permanent pacing system in a pediatric patient are listed in Table 18.7 (173).

TABLE 18.7 Indications for Pacing in the Pediatric Population

Class I (Recommended)

1. Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output
2. SND with correlation of symptoms during age-inappropriate bradycardia
3. Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery
4. Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction
5. Congenital third-degree AV block in the infant with a ventricular rate <55 bpm or with congenital heart disease and a ventricular rate <70 bpm

Class IIa (Is Reasonable)

1. Patients with congenital heart disease and sinus bradycardia (intrinsic or antiarrhythmic induced) for the prevention of recurrent episodes of intra-atrial reentrant tachycardia
2. Congenital third-degree AV block beyond the 1st year of life with an average heart rate <50 bpm, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or associated with symptoms due to chronotropic incompetence
3. Sinus bradycardia with complex congenital heart disease with a resting heart rate <40 bpm or pauses in ventricular rate longer than 3 s
4. Patients with congenital heart disease and impaired hemodynamics due to sinus bradycardia or loss of AV synchrony.
5. Unexplained syncope in the patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block after a careful evaluation to exclude other causes of syncope.

Class IIb (May Be Considered)

1. Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block because of the long-term risk for development of AV block
2. Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function
3. Asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate <40 bpm or pauses in ventricular rate longer than 3 s

Class III (Not Recommended)

1. Transient postoperative AV block with return of normal AV conduction in the otherwise asymptomatic patient
2. Asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of prior transient CAVB.
3. Asymptomatic type I second-degree AV block.
4. Asymptomatic sinus bradycardia with the longest relative risk interval <3 seconds and a minimum heart rate more than 40 bpm

Adapted from Epstein A, DiMarco J, Ellenbogen K, et al. ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities. *J Am Coll Cardiol* 2008;5:E1–E62.

TABLE 18.8 Indications for Implantable Cardioverter-Defibrillator (ICD) Placement in Pediatric Patients**Class I (Recommended)**

1. ICD implantation is indicated in the survivor of cardiac arrest after evaluation to define the cause of the event and to exclude any reversible causes
2. ICD implantation is indicated for patients with symptomatic sustained VT in association with congenital heart disease who have undergone hemodynamic and electrophysiologic evaluation. Catheter ablation or surgical repair may offer possible alternatives in carefully selected patients

Class IIa (Is Reasonable)

1. ICD implantation is reasonable for patients with congenital heart disease with recurrent syncope of undetermined origin in the presence of either ventricular dysfunction or inducible ventricular arrhythmias at electrophysiologic study

Class IIb (May Be Considered)

1. ICD implantation may be considered for patients with recurrent syncope associated with complex congenital heart disease and advanced systemic ventricular dysfunction when thorough invasive and noninvasive investigations have failed to define a cause

Class III (Not Recommended)

1. ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet specific ICD implantation criteria
2. ICD therapy is not indicated for patients with incessant VT or ventricular fibrillation
3. ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up
4. ICD therapy is not indicated for NYHA Class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or implantation of a biventricular pacing device that incorporates both pacing and defibrillation capabilities.
5. ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease
6. ICD therapy is not indicated when ventricular fibrillation or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with WPW syndrome, right ventricular or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease)
7. ICD therapy is not indicated for patients with ventricular tachyarrhythmias due to a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma)

Adapted from Epstein A, DiMarco J, Ellenbogen K, et al. ACC/AHA/HRS 2008 Guidelines for device-based therapy of cardiac rhythm abnormalities. *J Am Coll Cardiol* 2008;51:E1–E62.

ICD therapy is the standard of care for prevention of sudden cardiac death in all age groups. The implantation of an ICD provides additional treatment in patients who experience life-threatening arrhythmias. The efficacy of ICDs to terminate ventricular arrhythmias has been proven in pediatric patients (174). The current indications for ICD implantation in pediatric patients and adults with congenital heart disease are based on data derived from adult studies and are located in Table 18.8. The main reason for ICD implantation has evolved over the years from secondary prevention of sudden cardiac death to their current use for primary prevention in patients with an increased risk for sudden death.

Biventricular Pacing

Cardiac resynchronization therapy (CRT) uses two separate pacing leads in the right and left ventricle to restore electrical and mechanical synchrony in patients with an intraventricular conduction delay. Despite varying causes of dyssynchrony, CRT has been successfully performed with good results. Although criteria for resynchronization have yet to be determined, research is currently being performed to guide clinicians as to which patients can benefit from this new technology. However,

several case series have indicated that CRT produces excellent results in children with a response rate around 85% to 90%, not only serving as a viable bridge to transplantation but also allowing many to be removed from transplantation lists because of improvement in symptoms and function (175–177). However, there is a relatively high complication rate for the procedure (including procedural deaths) and patients may require a surgical approach to place one or both pacing leads.

Follow-Up

After the implantation of a rhythm management device, they require close follow-up to ensure they are working appropriately. After initial implantation, the patient may be reevaluated relatively soon after implantation to ensure that the device is not infected and the incision is healing well. After this brief initial follow-up, patients then generally are evaluated in the office at 1 to 3 months after implantation and then at least once a year for the life of the device. During these visits, the device is interrogated to make sure the programming parameters are appropriate for the patient's age and lifestyle and the settings are optimized to maximize battery longevity. In addition to device interrogation, patients may have an ECG, Holter

monitor, chest x-ray (particularly during times of rapid linear growth), and exercise stress test to evaluate rate responsiveness and pacemaker function. Between visits, patient may perform device checks remotely through a telephone or wireless connection. These “transtelephonic checks” can give important information about battery status or problems with the device or lead. In addition, actual tracings of arrhythmias may be transmitted in patients with defibrillators who have had an ICD shock.

SUMMARY

Tachyarrhythmias and bradyarrhythmias are not uncommon in the pediatric age group. They have a wide variety of presentations and treatments. As our knowledge about these conditions continues to progress, specific therapies can be directed to diagnosing, curing, or preventing these conditions.

Pediatric Cardiac Intensive Care

Physiology of the Preterm and Term Infant

Timothy M. Hoffman ■ Stephen E. Welty

INTRODUCTION

Approach to the care of the neonate with congenital heart disease is multidisciplinary. Regardless of where the patient is cared for (neonatal intensive care unit, cardiac intensive care unit) a firm understanding of neonatal physiology and development by the managing medical team is imperative to provide state-of-the-art interdisciplinary care. This chapter provides a unique perspective of the neonate from a multi-organ system approach. Cardiac lesion-specific data are outlined throughout the textbook; therefore this chapter does not include a discussion of these conditions. Instead, this chapter focuses on the complex interactions of multiple organ systems in neonates who also have congenital heart disease. In addition, an overview of lung development and the management of a patent ductus arteriosus in premature infants is presented.

TRANSITIONAL CIRCULATION

With the onset of spontaneous respiration at the time of birth, the low-resistance placenta is removed from the circulation, thus increasing systemic vascular resistance. Expansion of the lungs elicits an immediate decrease in the pulmonary vascular resistance as a result of physical recruitment of pulmonary vasculature and vasodilation of the pulmonary arteriolar bed in response to an elevated oxygen content. In turn, the shift of the systemic and pulmonary vascular resistances causes a reversal of flow of the ductus arteriosus from right to left to predominantly left to right. In theory, this change from fetal circulation causes an increase in pulmonary blood flow and a decrease in systemic venous return due to the lack of umbilical venous flow. Left atrial pressure increases and eventually exceeds the pressure in the right atrium leading to closure of the foramen ovale flap against the crista dividens, eliminating shunting at the atrial level. All of these alterations may be influenced by disease processes that affect the systemic and pulmonary vascular resistances, inhibiting the usual transition

to adult circulation (1,2). Additionally, after the initial precipitous fall in pulmonary vascular resistance, it continues to fall gradually in the first 48 hours of life and takes several weeks to fall to adult levels. In a normal neonate, the ductus generally closes functionally within several days of life.

PATENT DUCTUS ARTERIOSUS

Classic studies by Gittenburger-De Groot have described the sequence of events that occur in the infants that lead to functional and anatomic closure of the ductus arteriosus (3). The molecular events explaining closure and the predisposition of the ductus to remain patent in premature infants have been described (4–8). Ductal closure is dependent upon an initial ductal constriction which results from the development of hypoxia within the ductal media. Hypoxia mediates a series of molecular events that then lead to disruption of the internal elastic lamina and endothelial cell. Smooth muscle cells proliferate forming intimal mounds that impinge on the ductal lumen, ultimately leading to its anatomic closure. In premature infants, ductal constriction is essential for anatomical closure of the ductus arteriosus. But this alone may not be sufficient for ductal closure. Hypoxia in the muscular media may not occur and the post-constriction sequence fails to follow. Thus, premature infants may present with a symptomatic patent ductus arteriosus (PDA), especially those who are <30 weeks of gestation.

The incidence of PDA in premature infants is inversely related to gestational age. In a recent multicenter trial of indomethacin prophylaxis in premature infants weighing <1,000 g, the incidence of PDA in the placebo group was 50% (9). Premature infants with a PDA may present with classic findings of a left-to-right shunting lesion. In this case, infants typically have a systolic murmur, increased left precordial activity, sometimes with an associated thrill, bounding pulses, and a wide pulse pressure that also may be evident on umbilical arterial waveform tracings. Unfortunately, many infants with

a physiologically significant PDA may not have these findings. Thus there should be a high index of suspicion for a PDA even without classic physical findings in a premature infant who has lung disease. Doppler-echocardiography is the gold standard for diagnosing a PDA, and should be performed before treatment decisions are made.

Physiology of the PDA is secondary to overperfusion of the lung and possibly underperfusion of the systemic circulation. Infants' lungs are fully recruited at rest so that any increase in flow from left-to-right shunts predictably increases fluid filtration in the lung (10). Increased fluid filtration will lead to pulmonary edema if it exceeds the ability of the lymphatics to remove fluid, and pulmonary edema is frequently associated with pulmonary overcirculation from a PDA. The PDA may also steal from the systemic circulation. Animal studies have shown that even small shunts underperfuse systemic organs (10). Studies in extremely premature infants with a hemodynamically significant PDA observed that although total left ventricular output was increased, flow was decreased in the abdominal aorta, celiac, mesenteric, and renal arteries, while there were no differences in the anterior cerebral artery flow (11). While the changes in acute physiology are concerning, the effect of a PDA on the outcome of premature infants and the management of a PDA is controversial (12,13).

The management of the PDA in premature infants has changed dramatically over the last decade. The uniform findings from animal studies are that a PDA is associated with underperfusion of the systemic circulation and overcirculation of the pulmonary bed with the development of pulmonary edema (10,11). If these findings can be extrapolated to premature infants who weigh <1,000 g and approaches to preventing or treating the PDA lacked significant toxicity, it would support taking aggressive steps to prevent the development of a significant PDA, or at the very least, for treatment of these infants with a clinically significant PDA. Furthermore, epidemiologic data indicate that premature infants who develop a clinically significant PDA have higher rates of mortality and morbidity than do comparably sized infants who do not develop a significant PDA (14,15).

Treatment approaches include surgical ligation, pharmacologic treatment with cyclooxygenase inhibitors, or supportive medical management with fluid restriction, cardiovascular support, and therapy with diuretics. As recently as 1996, an analysis of strategies including prophylaxis, early treatment, and late treatment after overt symptoms indicated that the most reasonable approach to the PDA in premature infants is using indomethacin either prophylactically in high-risk populations or within the first few days of life when the PDA became evident prior to the development of overt symptoms (16). However, there have been marked improvements in perinatal care including an increased emphasis on the treatment of mothers who are at risk for delivering a premature infant with antenatal steroids (17,18). Likewise a more aggressive approach to noninvasive respiratory support strategies allows even premature infants born <1,000 g to be frequently not supported with pressors or mechanical ventilation in the first 24 hours of life. In this changing clinical context, aggressive treatment of the PDA in an infant with minimal lung disease and support has come into question. A recently published meta-analysis has concluded that prophylactic treatment of premature infants with cyclooxygenase inhibitors, while reducing the need for surgical ligation of the ductus and lowering the incidence of intraventricular hemorrhage, elicited no differences in survival or neurodevelopmental outcomes (19). Thus, a reasonable interpretation of the present clinical evidence supports the conclusion that the beneficial effect in closing the ductus in a population of infants who would have developed a symptomatic PDA may be offset by the deleterious effects of treating some infants

who would not have developed a PDA with a potent class of drugs with a significant frequency of side effects. Thus, treatment of a hemodynamically significant PDA appears to be the most prudent approach in extremely low birth weight infants. A recent meta-analysis comparing indomethacin with ibuprofen demonstrated no difference in efficacy in patients treated with ibuprofen, yet yielded a significantly lower incidence of side effects (20). This meta-analysis may lead to the conclusion that, at present, ibuprofen is the best treatment option for those with a symptomatic PDA. However, a recent analysis combining data from American and European studies found that ibuprofen therapy was associated with a greater risk of the development of bronchopulmonary dysplasia (BPD) than indomethacin therapy (21). Thus, the optimal choice of cyclooxygenase inhibitors remains unanswered.

Treatment of a PDA has taken a risk-based approach. If a premature infant with echocardiographic evidence of a PDA in the first week of life requires mechanical ventilation for support of lung disease that cannot be attributed to respiratory distress syndrome (RDS), treatment is warranted and a course of ibuprofen is probably the preferred choice. Furthermore, independent of the amount of cardiopulmonary support required, if a premature infant has clinical evidence of a PDA, such as wide pulse pressures, an active precordium, or a loud murmur and an echocardiogram demonstrates a ductus with evidence of left atrial or left ventricular enlargement, treatment is also warranted.

The role of surgical ligation in infants has become even less clear than the pharmacologic approach to treatment of a PDA. There is no evidence that early aggressive treatment with PDA ligation improves clinical outcomes (22), and recent evidence suggests that late ligation of a significant ductus arteriosus is associated with concerning long-term neurodevelopmental outcomes (23). These data do not exclude the need for surgical ligation, but rather may highlight the point that extremely premature infants who have a PDA evident after the first week of life define a population of infants at extremely high risk for long-term morbidity. However, based on the concerns about surgery, many clinicians choose to treat infants failing a course of cyclooxygenase inhibitors with fluid restriction and diuretics and defer ligation for the most symptomatic infants.

Lung Development

Lung development from the embryonic phase to the alveolar phase has been studied in humans and in many mammals (24–27). Furthermore, the molecular basis for lung development continues to be elucidated and a discussion of the mechanisms for lung development is beyond the scope of this chapter. However, since lung development proceeds through postnatal life for several years, understanding the effects on lung development of congenital heart disease, its treatment, and supportive medical care for lung disease is important. Overall lung development can be optimized in infants with respiratory disease and heart disease whether they are born prematurely or not.

Infants born as early as 23 weeks of gestation can survive. At 23 weeks of gestation, infants are still in the cannicular phase of lung development, which continues through 26 weeks of gestation. Despite the relatively immature lung architecture, including no identifiable alveoli and a thickened alveolar interstitium with a double capillary network, the lung can subserve enough air exchange function for the infant to survive. The sacular phase of lung development extends from 27 to 36 weeks of gestation and the alveolar phase starts at 37 weeks and proceeds through approximately 3 years of postnatal age. In infants born prematurely without heart disease, supportive care with mechanical ventilation and supplemental oxygen frequently

injures the lung and predisposes the infant to the development of chronic BPD (28). Furthermore, perinatal inflammation of the lung is frequently observed in premature infants, which also can injure the lung profoundly (29). The injury caused by lung support and/or inflammation leads to an arrest of lung development, and the lung function abnormalities can persist for years (30,31). Thus in infants, especially premature infants, who have heart disease and require supportive care delivered to the respiratory system, therapies should be pursued that limit lung injury and thereby limit aberrations in lung development, similar to treatment strategies being explored in infants born prematurely who do not have heart disease.

The most important intervention to improve the outcomes of premature infants is the administration of antenatal steroids to mothers who are at risk of delivering a premature infant. The landmark study by Liggins and Howie demonstrated a beneficial effect of antenatal steroids given to mothers who delivered infants at <34 weeks of gestation (32). These results have been verified by many other randomized, double-blinded, placebo control trials. While the initial studies focused on decreasing the incidence of respiratory distress, there was also evidence that antenatal corticosteroid (ACS) administration decreased mortality and other morbidities in premature infants (33–35). ACS administration enhanced lung and circulatory development. So much so that an NIH consensus statement stated strongly that ACS should be given to mothers with threatened premature delivery between 24 and 34 weeks of gestation (17). Details for ACS administration can be found in the NIH consensus statement. There is no present evidence that supports repeat ACS administration to those mothers who do not deliver within 1 week of steroid administration (18).

Surfactant administration has been shown to improve outcomes in premature infants. Exogenous surfactant has been given in prophylactic and rescue modes. In the prophylaxis studies of premature infants who were at high risk of having RDS, surfactant administration was given within 15 to 20 minutes of birth. This led to lower mortality rates and less morbidity than was seen in infants who were given surfactant after the diagnosis of RDS was established (selective) (36). These differences are less relevant in more mature infants. Thus, infants born after 30 weeks of gestation can be assessed for development of RDS and if RDS is present, surfactant should be delivered in the rescue mode (37).

In the last decade, as the antenatal steroid administration to mothers has increased and the expertise of noninvasive respiratory support has been enhanced, many infants, even extremely premature infants, are delivered with minimal lung disease so that a trial of noninvasive respiratory support with nasal continuous positive airway pressure (CPAP) may be reasonable. In 2008, the COIN (continuous positive airway pressure on intubation at birth) trial was published in which 610 infants between 25 and 28 weeks were randomized to either CPAP or intubation with surfactant at birth (38). While there were some differences favoring the CPAP group at 28 days of life, the outcomes at 36 weeks postmenstrual age for morbidity and mortality were not different. Another study by the SUPPORT study group (surfactant positive pressure and pulse oximetry randomized trial) enrolled 1,310 infants between 24 and 27 weeks of gestation which randomized similarly to the COIN study. The study results showed no statistically significant differences in the composite outcome of death or BPD at 36 weeks postmenstrual age (39). The combination of these findings suggest that infants born at 24 weeks of gestation up to 28 weeks of gestation who were exposed to maternal ACS and are vigorous at birth may be supported with CPAP without prophylactic surfactant. However, if the infants' oxygen requirement rises to >40%, administration of surfactant should then be considered.

Other therapeutic measures in premature infants that help to prevent development of BPD include: (a) monitoring to

prevent hyperoxemia and minimize exposure to supplemental oxygen and mechanical ventilation, (b) fluid restriction in the first few days of life (40), and (c) the institution of aggressive and early parenteral and enteral nutrition. The combination of therapies just discussed is supported in premature infants without congenital heart disease. However, there are no reports regarding the impact of congenital heart disease on lung development in premature infants, or on postnatal lung development in term infants. Acute management of premature infants with congenital heart disease is thus extrapolated from what has been observed in premature infants without heart disease.

PULMONARY HYPERTENSION

Abnormalities of smooth muscle development frequently influence acute cardiopulmonary physiology in newborn infants. Pulmonary hypertension is frequently present when there is abnormal vascular smooth muscle development. Pulmonary hypertension presenting in the newborn period is classified into three separate categories based on the underlying mechanisms for the development of the disorder. The three categories include underdevelopment, maldevelopment, and maladaptive forms. In this classification only underdevelopment and maldevelopment pulmonary hypertension are associated with abnormalities of smooth muscle development. In fetal development, airway branching and smooth muscle development occur in parallel in an environment where pulmonary vascular resistance is high and blood flow is low. In normal lung development, smooth muscle development around the vasculature extends to the level of the respiratory bronchiole. When the fetus is compromised by poor placental function and high placental vascular resistance, smooth muscle development is altered so that it extends further distally in the pulmonary vasculature and is thicker. The thickening occurs as a combination of intimal and adventitial thickening which gives rise to maldevelopment pulmonary hypertension (41). Underdevelopment pulmonary hypertension is associated with pulmonary hypoplasia which leads to a decreased cross-sectional surface area of the pulmonary vascular bed. In addition, underdevelopment pulmonary hypertension is frequently associated with maldevelopment of the pulmonary vasculature (42).

Infants with maldevelopment pulmonary hypertension frequently present with evidence of poor placental function and poor adaptation to their extrauterine environment. Evidence for poor placental function may present as a poorly nourished infant with evidence of fetal weight loss. The perinatal period is often associated with marked fetal distress because labor taxes the function of the compromised placenta. Thick meconium may be noted and the infant may be depressed or asphyxiated at birth. Even without these adverse perinatal events, the abnormal pulmonary vascular bed may not allow the normal rapid initial drop in pulmonary vascular resistance and subsequent increase in pulmonary blood flow which are essential for appropriate cardiopulmonary physiology and adaptation to an adult-type circulation in series with high pulmonary blood flow and air exchange in the lung.

RESPIRATORY PHYSIOLOGY

In the fetus, the organ of respiration is the placenta and the lung is a high resistance, minimal flow, liquid-filled organ. Furthermore, the fetal lung secretes fluid into the airway (43). During late gestation surfactant production increases in preparation for the lung becoming the organ of respiration, and the

molecular processes essential for fluid absorption are induced (44). This induction is enhanced by labor. At delivery with the onset of regular respirations, optimal air exchange physiology occurs when lung volume is adequate and pulmonary vascular resistance drops allowing the resultant increase in blood flow.

Disorders of transition occur when any one of the three critical steps do not occur or are delayed. The three disorders of transition are: (a) transient tachypnea of the newborn, which occurs when the removal of lung water is delayed, (b) RDS, formerly known as hyaline membrane disease, and (c) pulmonary hypertension of the newborn which occurs when the normal drop in pulmonary vascular resistance does not occur or is delayed. Each of these disorders has a characteristic physiology which leads to alterations in air exchange. In most cases, the primary aberration is hypoxemia, even though the physiology by which this aberration occurs is different.

In order to understand respiratory physiology of the newborn it is critical to understand some of the physical properties of the lung that determine ventilation. The equation of motion describes the properties of the lung important for proper ventilation:

$$\Delta P = 1/cV + R\dot{V} + I\ddot{V}$$

where P represents the pressure applied to the respiratory system, C is compliance which is defined as the change in volume divided by the change in pressure, describing the elastance of the respiratory system, V is volume, R is resistance, \dot{V} is the flow, I is inductance, and \ddot{V} is acceleration. Thus, properties of the lung can be divided into the static properties of the lung which are measured when there is no flow and is dependent on the compliance term in the equation of motion, and the resistive properties of the lung, which are measured when there is flow and are dependent on the resistance term in the equation of motion and inductance which, in most cases is thought to be negligible relative to the static and resistive properties and is therefore ignored. In well newborn infants the compliance is normal and the resistance is low so that minimal effort or energy is needed to provide reasonable ventilation to the respiratory system independent of whether the infant is doing the work or if the infant requires mechanical ventilation.

In infants with primary lung disease, the most common biochemical derangement is arterial hypoxemia. The mechanisms for significant hypoxemia in infants with lung disease are primarily ventilation-perfusion abnormalities and/or right-to-left shunting (both intrapulmonary and extrapulmonary). The sum of the shunt fraction and the ventilation-perfusion inequalities is the venous admixture. The venous admixture is higher in newborns even without lung disease (45,46). In parenchymal lung disease, the venous admixture increases dramatically and arterial hypoxemia may become profound. Furthermore, the relative proportion of the shunt fraction and V/Q abnormalities is dynamic such that as ventilation of the lung improves it has been shown that the shunt fraction and low V/Q compartments may be affected independently or in tandem. The primary strategy in infants with lung disease is to improve the function of the low V/Q compartment. Administration of supplemental oxygen may improve the oxygen concentration in the terminal air units and may relieve hypoxic pulmonary vasoconstriction, in which case improvement in oxygenation occurs by decreasing the size of the shunt compartment with no effect on the low V/Q compartment. Improving the ventilation to the low V/Q compartment of the lung frequently addresses both the shunt compartment and the low V/Q compartment. In this case, these strategies may recruit the shunt compartment by improving ventilation, raising the partial pressure of oxygen, and relieving hypoxic pulmonary vasoconstriction. The same

strategies may recruit the former low V/Q compartment into the normal V/Q compartment at the same time. Thus while administration of supplemental oxygen is relatively safe and may decrease the shunt compartment, supportive strategies to safely increase ventilation to the most diseased areas of the lung may affect the shunt compartment and low V/Q compartment simultaneously.

The most appropriate strategy to support the respiratory system in the diseased lung depends on the physical properties of the lung, including the static properties and the resistive properties. It is appropriate to bear in mind that supportive measures which improve the function of the diseased lung do not improve the underlying disorder. In fact, supplemental oxygen is toxic and the application of positive pressure to the lung causes injury (47). When positive pressure is administered the strategy utilized should be tailored to the abnormalities in the lung. In lung diseases dominated by low respiratory system compliance, such as RDS or hyaline membrane disease, the airways and airspaces fill and empty quickly so that if mechanical ventilation is utilized, a fast rate-low tidal volume ventilation strategy should be used and has been associated with better outcomes (48). In diseases dominated by high airway resistance, a ventilator strategy using a slower rate with slightly higher tidal volume ventilation is more successful. Examples of such diseases include meconium aspiration and BPD. In infants with RDS, the safest and most efficient technique to improve lung physiology is by increasing the mean airway pressure and the safest and most efficient technique to increase mean airway pressure is to increase the end pressure (49). In fact, many infants with RDS can be managed with CPAP only which is the preferable mode in relatively mature infants (50,51).

CARDIOPULMONARY INTERACTION

The pulmonary vasculature in the lung of infants is fully recruited at rest and is particularly predisposed to the development of pulmonary edema when flow is increased via anatomic left-to-right shunts. The rate of fluid filtration (Q_f) in the lung or any other organ or vascular bed is governed by the Frank-Starling equation:

$$Q_f = K_f \left[(P_{mv} - P_{pmv}) - \sigma (\pi_{mv} - \pi_{pmv}) \right]$$

where K_f is hydraulic conductance, P_{mv} is hydrostatic pressure in the microvasculature, P_{pmv} is hydrostatic pressure in the peri-microvascular space, σ (sigma) is the reflection coefficient, π_{mv} is oncotic pressure in the microvasculature, and π_{pmv} is oncotic pressure in the perimicrovascular space.

Abnormalities in K_f and P_{mv} are the dominant variables in fluid filtration. K_f is a function of the number and size of the pores in the endothelial cell layer. Disorders that injure endothelial cells markedly increase K_f and fluid filtration (52). When K_f is increased and leads to pulmonary edema, it is characterized as permeability pulmonary edema. There are many disorders that increase K_f and lead to pulmonary edema, but the most common disorders confronted in the newborn period include RDS and sepsis both of which are frequently associated with lung inflammation and a component of lung edema secondary to inflammatory injury (53,54). Unfortunately mechanical ventilation has the potential to induce lung inflammation, thus careful supportive care to limit lung inflammation is imperative.

High pressure pulmonary edema is common in the newborn period, since the lung of the newborn is fully recruited at rest, left-to-right shunts increase fluid filtration substantially

(55,56), and elevations of left atrial pressure also increases filtration. The equation for P_{mv} is:

$$P_{mv} = P_{LA} + c(P_{PA} - P_{LA})$$

where c is equal to a constant between 0 and 1 and PA and LA are pulmonary arterial and left atrial, respectively. This equation illustrates the significant impact of elevated P_{LA} in lung fluid filtration. P_{LA} (or pulmonary venous pressure) can be particularly elevated in some forms of congenital heart disease (e.g., obstructed anomalous pulmonary venous connection, mitral valve disease, or hypoplastic left heart syndrome). Fluid accumulation in the lung can only occur when fluid filtration exceeds lymphatic function which returns filtered fluid to the venous circulation ($Q_f > Q_L$). Q_L is dependent on intrinsic contractility of the lymphatics in the lung and on the right atrial pressure. Right atrial pressure may be elevated in infants with lung disease enhancing fluid accumulation in the lung and the pressures at which lymphatic flow is impaired are lower in the fetus and newborn than in older patients. In summary, infants with lung disease and/or heart diseases are more predisposed to develop pulmonary edema than in any other age-group because increases in flow are invariably associated with increased microvascular pressure and developmentally impaired lymphatic function is frequently incapable of meeting the demands of increased fluid filtration.

The effects of pulmonary edema on respiratory physiology are dependent on the location of the edema fluid. Typically fluid filtration occurs in the alveolar capillary, but hydrostatic forces in the lung favor fluid accumulation in the extra-alveolar interstitium (57). The extra-alveolar interstitium contains airways so that fluid can compress the airways leading to constriction and increased airway resistance (58). This explains the finding of cardiac asthma and increased airway resistance with pulmonary edema. Decreased respiratory system compliance can also occur with pulmonary edema, primarily when accumulation occurs in the alveolar space and impairs surfactant function. It is difficult to filter fluid to the extent that fluid accumulates in the alveolar space because respiratory epithelial cells are excellent barriers to fluid egress and they actively pump fluid from the alveolar space into the interstitium (59). The extra-alveolar interstitium can accumulate excessive fluid before it egresses into the alveolar space. However, the lung is more susceptible to alveolar fluid accumulation when increased fluid filtration is associated with injury to respiratory epithelial cells.

Treatment for pulmonary edema is almost entirely supportive, and includes measures to lower P_{mv} or to support the respiratory system by applying positive pressure. Measures to decrease P_{mv} include reducing pulmonary blood flow by decreasing left-to-right shunts, or by decreasing circulating blood volume. Decreasing fluid administration is a reasonable short-term maneuver to decrease fluid filtration, but only if the fluid restriction does not impair the delivery of adequate nutrition. Therapy with diuretics may also reduce P_{mv} by decreasing circulating blood volume. While equipotent doses of diuretics improve lung function by decreasing lung water, furosemide has the additional effect of pulmonary dilation (60) which lowers P_{mv} further. Thus this diuretic is more effective for pulmonary edema than are equipotent doses of other diuretics. Pulmonary edema may accumulate to the extent that pressure support to the lung is necessary. The delivery of positive pressure does not decrease fluid accumulation in the lung. It simply improves the acute physiology, usually by improving V/Q mismatching (61,62) by improving ventilation to the low V/Q compartment in the lung. Decreasing pulmonary edema by decreasing K_f or by improving lymphatic function would be optimal, but measures to consistently achieve these improvements have not been described.

Abnormalities of pulmonary vascular physiology are confined primarily to inappropriate vasoconstriction. Persistent pulmonary hypertension in the newborn occurs when the normal decrease in pulmonary vascular resistance that occurs at birth does not occur and can be a result of underdevelopment, maldevelopment, or maladaptive forms of pulmonary vascular disease as described previously. Pulmonary hypertension in the newborn frequently presents with significant hypoxia because of right-to-left shunting at the fetal shunt pathways at the atrial and ductal levels. Pulmonary constriction is usually on the arterial side of the circuit so that therapies which dilate the pulmonary circuit may improve hypoxemia without increasing fluid filtration if the venous circuit is normal.

Pulmonary hypertension was the most common reason for placing infants on extracorporeal life support because specific pulmonary vasodilators had not been identified. However, inhaled nitric oxide has unequivocally improved the abnormal pulmonary physiology observed in infants with pulmonary hypertension. In several large randomized trials, nitric oxide was effective at reducing the incidence of death or the need for extracorporeal support (63). Inhaled nitric oxide was approved for utilization in infants with hypoxic respiratory failure in 1997 and was restricted to infants at or beyond 34 weeks of gestation. The utilization of this drug has meant that treatments previously used to support these infants, including high concentrations of oxygen and/or induced alkalosis, are contraindicated. Typical indications for the utilization of inhaled nitric oxide in term or near-term infants are respiratory failure as indicated by an oxygenation index of >20 to 25 ($OI = FiO_2 \times \text{mean airway pressure} \times 100/PaO_2$) and evidence of pulmonary hypertension from Doppler-echocardiography. Supportive efforts with mechanical ventilation and/or administration of surfactant that improve lung inflation improve the efficacy of inhaled nitric oxide (64). Nitric oxide is started at 20 ppm and is decreased in 50% decrements when supplemental oxygen requirements decrease substantially, usually to $<50\%$. When the dose of nitric oxide is 5 ppm, further decrements must be done cautiously as rebound pulmonary hypertension has been described in this range (65). Infants <34 weeks of gestation may also present with hypoxic respiratory failure and recent trials have been published suggesting that these infants may also benefit from treatment with nitric oxide (66–68). However, nitric oxide therapy has not yet been approved for these infants.

HYPERTROPHIC CARDIOMYOPATHY IN INFANTS OF DIABETIC MOTHERS

Maternal diabetes poses several risks to both the fetus and the newborn infant including fetal growth alterations, metabolic derangements, RDS, elevated pulmonary vascular resistance, congenital anomalies, and hypertrophic cardiomyopathy (69). From a cardiovascular standpoint, fetal heart development may be altered with reports of a 15% incidence of congenital heart disease in this population (70). In animal studies involving diabetes during pregnancy, abnormal gene expression has been shown to impair cardiogenesis in the fetus during the first trimester (71,72). During the second and third trimester, maternal diabetes has been associated with the development of hypertrophic cardiomyopathy that generally manifests as asymmetric septal hypertrophy. The incidence of hypertrophic cardiomyopathy has been reported to be approximately 30% to 38% in infants of diabetic mothers (70,73–74). The clinical presentation varies considerably with a spectrum from a limited process that abates within months of birth to severe cardiac compromise leading to mortality (74). Cardiac issues

have been noted in fetuses regardless of type of maternal diabetes. A recent study noted a 50% rate of newborn hypertrophic cardiomyopathy in type 1 diabetic mothers; however, a 25% rate was noted in infants of type 2 diabetic mothers (74). In contrast, an approximate rate of 2% was noted in infants of mothers with gestational diabetes (74). A comparison of those with well-controlled gestational diabetes to normal controls revealed mild hypertrophic changes in the diabetic group. However, these hypertrophic changes were not associated with significant pathology including no left ventricular outflow tract obstruction although minor changes in right ventricular diastolic function were observed (75).

The exact etiology of this hypertrophic change is unknown but plausible evidence suggests that hyperinsulinism triggers hyperplasia and hypertrophy of myocardial cells (76,77). Studies have noted increased maternal serum insulin-like growth factor I (IGF-I) at the time of delivery associated with neonatal hypertrophic cardiomyopathy (78,79). Clinical correlation of the neonatal hypertrophic cardiomyopathy to a history of maternal diabetes is paramount; however if the history is not clear, rare potential associations should be evaluated including Fabry disease, Costello syndrome, and Pompe disease (80–82).

RESPIRATORY SYNCYTIAL VIRUS

Infections caused by respiratory syncytial virus (RSV) create significant morbidity and mortality for patients at high risk including premature infants, infants with BPD, and infants with complicated hemodynamically significant congenital heart disease. The overall hospitalization rate for patients <1 year of age with RSV is 2% annually. Those at high risk experience approximately five times the rate of admissions for RSV-related illness as compared to those not at high risk (83–86). No active immunization program has ever been shown to be efficacious for RSV (87,88); however passive immunity with palivizumab has been shown to decrease RSV infections in high-risk infants. Palivizumab is a monoclonal antibody directed against the F protein of RSV (89,90). Palivizumab has been shown to decrease RSV-related hospitalizations in patients with hemodynamically significant congenital heart disease (91). Monthly intramuscular injections (15 mg/kg) during RSV season in this patient population yielded a 45% reduction in RSV-related hospitalizations, a 56% reduction in total days of RSV-related hospitalizations, and a 73% reduction in RSV hospitalization days with increased supplemental oxygen (91). Evidence exists in patients who receive palivizumab and then undergo surgery involving cardiopulmonary bypass that the levels of monoclonal antibody decrease dramatically. Therefore, after surgery involving cardiopulmonary bypass, dosing should be repeated at a safe time in the postoperative period.

NEUROLOGY

The fetal development of the brain and heart occur simultaneously (92). Therefore, impaired brain maturation and susceptibility to injury has been shown in patients with various forms of congenital heart disease (93,94). A case-control study showed an increased risk of microcephaly, as defined by a head circumference less than the third percentile, in newborns with tetralogy of Fallot, hypoplastic left heart syndrome, and coarctation/arch anomalies (93). Intrauterine hypoxia may lead to central nervous system damage (93). In patients with hypoplastic left heart syndrome and transposition of the great arteries, neonates were found to have smaller and less mature brains

than expected (94). A total maturation score was previously validated and used in this study which is a semiquantitative anatomic scoring system. This score utilizes four parameters to assess whole-brain maturity which include myelination, cortical infolding, involution of the glial cell migration bands, and presence of germinal matrix tissue (94). Magnetic resonance imaging (MRI) and magnetic resonance spectroscopy in neonates with congenital heart disease have shown white matter abnormalities before any cardiac intervention (95,96). Impaired brain maturation may lead to susceptibility to poor neurologic outcomes. Observers have noted that decreased cerebral oxygen delivery perioperatively, as evidenced by near-infrared spectroscopy, is associated with an abnormal psychomotor development index and MRI abnormalities (97).

Many institutions arrange for a head ultrasound study on patients prior to intervention for critical congenital heart disease. The head ultrasound is used to determine anatomical issues, hemorrhage, ischemia, hydrocephalus, and atrophy. Although this test is routinely performed, it is often replaced by other imaging studies if there is an abnormality. Cranial ultrasound in patients with congenital heart disease has shown abnormalities in as high as 42% of those screened (98). Findings included widened ventricular and/or subarachnoid spaces, lenticulostriate vasculopathy, calcification of basal nuclei, and ischemia. Patients with left-sided obstructive lesions seem to have a higher incidence of brain abnormalities (98). There is increasing concern that certain lesions may impact cerebral blood flow not only postnatally but during fetal development. Cerebrovascular resistance is lower than normal in fetuses with hypoplastic left heart syndrome where cerebral perfusion occurs retrogradely via the ductus arteriosus (99). In patients with right-sided lesions, the cerebrovascular resistance is higher than those with left-sided obstructive lesions (99). This may have implications for neurologic development and subsequent susceptibility to adverse sequelae.

A recent study suggested that 19% of neurologic events occur preoperatively in patients with congenital heart disease (100). Predictive factors for a neurologic event, namely seizure, abnormal tone or choreoathetosis include an abnormal preoperative imaging study and an Apgar score of <7 at 5 minutes of life (100). MRI studies performed preoperatively, acutely postoperatively (within weeks of surgery), and then several months postoperatively have shown abnormalities. Preoperatively, patients mainly had periventricular leukomalacia (PVL) and infarct. Shortly after surgery, MRI examinations showed new PVL in 48%, new infarct in 19%, and a new parenchymal hemorrhage in 33% (101). The prevalence of stroke in one series was 10%, half of which occurred preoperatively (102). Lower birth weight, preoperative intubation, lower intraoperative hematocrit, and higher blood pressure at admission postoperatively were associated statistically with stroke (102). The majority were clinically silent with mechanisms felt to be due to either hypoperfusion or thromboembolism (102). Late MRI did show resolution of the findings in a subset of patients (103). Among 82 neonates who had undergone cardiac surgery, 54% had PVL but in older infants the incidence was only 4% (103). Early postoperative hypoxemia and hypotension (mainly diastolic) were noted to be risk factors (103).

Among survivors of congenital heart disease surgery, there are well-known late sequelae that may include learning disabilities, behavioral abnormalities, and attention deficit disorders (104,105). Many issues may lead to these findings including neuroprotection during cardiac surgery, use of deep hypothermic circulatory arrest, and postoperative decreased perfusion from low cardiac output syndrome. With the application of perioperative noninvasive, real-time neurologic monitoring, interdisciplinary teams caring for the patient may be able to intervene and prevent brain injury.

GASTROINTESTINAL SYSTEM

The development of the gastrointestinal system occurs as early as the 4th week of gestation. Mesenteric vascular system development parallels that of the intestine. Regulation of the mesenteric blood flow occurs at the arteriolar and precapillary level. Feeding causes hyperemia and as documented in animal studies (106), the neonate has lower intestinal vascular resistance than the fetus (107). Therefore, mesenteric blood flow is greater in the neonate than in the fetus until the second to fourth postnatal weeks, where intestinal resistance increases, with a corresponding decrease in blood flow and oxygen delivery. Of potential importance to those patients with critical congenital heart disease, mild hypoxia triggers dilation of the vascular bed and perfusion increases whereas severe hypoxia (PO_2 of 40 mmHg or less) causes vasoconstriction, tissue hypoxia, and potential ischemia (108).

The etiology of necrotizing enterocolitis (NEC) remains poorly understood, especially in term infants. Studies have shown that the majority of term newborns who develop NEC have underlying congenital disorders which are commonly either heart disease or endocrine disorders (109). A case control study of neonates with congenital heart disease showed that hypoplastic left heart syndrome (odds ratio 3.8), truncus arteriosus or aortopulmonary window (odds ratio 6.3) were independently associated with development of NEC (82). Additionally, in the same cohort, earlier gestational age at birth ($36.7 \text{ weeks} \pm 2.7 \text{ weeks}$), prematurity, and episodes of shock or low cardiac output were all risk factors (110). There was no documented mortality difference in patients who developed NEC versus those who did not; however the hospital stay was significantly higher in those who developed NEC. In patients with congenital heart disease who develop NEC, it is felt that mesenteric ischemia associated with a low perfusion state is the etiology; however, infectious associations are difficult to elucidate (111). A recent study suggests that patients with congenital heart disease who develop NEC have less risk of major short- and long-term adverse outcomes as compared to patients without heart disease (112). Patients with heart disease and NEC experienced less risk of perforation, need for a bowel operation, strictures, need for a stoma, sepsis, and short bowel syndrome (112). This suggests that NEC in those with cardiac disease may be a distinct entity. Cardiac lesions that elicit a difficult balance between pulmonary and systemic blood flow ($Q_p:Q_s$) whereby systemic perfusion can be limited due to a shift in the systemic and pulmonary vascular resistances pose a difficult dilemma to the intensivist regarding if and when to feed preoperatively and postoperatively.

Many patients with congenital heart disease also have heterotaxy (situs abnormalities). Situs inversus totalis is associated with intra-abdominal anomalies in over half of the patients. These may include duodenal atresia, biliary atresia, gastroschisis with malrotation, and tracheoesophageal fistula. Hiatal and diaphragmatic hernias are commonly noted in patients with right isomerism. Patients with left isomerism may have malrotation and biliary atresia (113). Intestinal malrotation may lead to gastrointestinal complications and require emergent surgery. It is debatable whether an elective Ladd procedure is warranted in all patients with malrotation once the cardiac condition is stabilized or appropriately palliated. Upper gastrointestinal contrast procedures likely should be recommended in all patients with heterotaxy and cardiac lesions to evaluate for intestinal malrotation (114).

RENAL

Glomerular filtration rate (GFR) in term neonates is $20 \text{ mL/min} \times 1.73 \text{ m}^2$ which is generally twice that of premature newborns (115). GFR improves over the first several weeks of life

in all newborns but the velocity at which it improves is less in premature infants. In term newborns, the GFR doubles in the first 2 weeks of life (116,117). These differences in GFR values among varying gestational age newborns impact the administration of medications that are primarily eliminated in the renal system. Digoxin dosages should be decreased for preterm infants. Creatinine is the most commonly used marker for renal function; however in neonates, interpretation must take into account several caveats (118). The creatinine level is falsely elevated at birth, reflecting maternal levels. Over the first several weeks of life in term neonates, creatinine decreases rapidly to expected levels (0.40 mg/dL). In those with extreme prematurity, a transient increase is noted over the first 4 days followed by a steady decrease over the next month of life. In premature infants, the transient rise in creatinine is caused by reabsorption of creatinine across renal tubules (119).

Because of the unique vascular supply of the renal medulla, the kidney is susceptible to hypoxic-ischemic injury. In congenital heart disease that either presents with decreased systemic blood flow in critical left-sided obstructive disease or a shift in $Q_p:Q_s$ with resultant decreased systemic oxygen delivery, renal function may be altered. Prolonged ischemia may result in impairment in sodium and water reabsorption as well as decreased GFR (120). Similarly, use of angiotensin converting enzyme (ACE) inhibitors may lower systemic blood pressure to the extent that hypoperfusion to the kidney occurs (121). Renal perfusion pressure may drop below the autoregulatory threshold and thus promote acute renal failure. Caution in dosing and monitoring of effects of ACE inhibitors in neonates is important to avoid adverse renal effects.

Many institutions advocate the use of umbilical catheters in newborns with critical congenital heart disease for access, monitoring, and acquisition of blood samples. Arterial lines have been associated with aortic and renal arterial complications including thrombosis. No definitive study has shown whether high or low umbilical arterial line placement affects the incidence of thrombotic complications; in fact, conflicting data exist (122,123). Both abdominal coarctation and renal artery stenosis have been reported as long-term complications of umbilical arterial lines. Umbilical venous lines are placed with the tip in the inferior vena cava cephalad to the hepatic and portal veins. Complications of these lines include thrombosis of the portal or hepatic venous systems or inferior vena caval thrombus. Renal vein thrombosis may occur and could manifest itself with symptoms of oliguria, anuria, hematuria, thrombocytopenia, acidosis, and hemolytic anemia (124). Hypertension can occur late after renal vein thrombosis but the magnitude of hypertension is much less than those with umbilical artery thrombosis.

CARDIAC INTERVENTION IN THE PREMATURE OR LOW BIRTH WEIGHT NEONATE

Recent reports suggest that aggressive attempts to treat congenital heart disease in either premature or of low birth weight infants are appropriate. Delaying surgery or cardiac catheter intervention for weight gain lead to longer hospital stays and increased morbidity (125). A meta-analysis of observational studies suggests that diagnosis is the factor that is most predictive of mortality as compared to low birth weight (126). However, data exist that suggest the ideal gestational age for a patient with critical congenital heart disease is 39 to 40 weeks of gestation (127). In 971 consecutive infants, patients born at 37 to 38 weeks of gestation had increased mortality, morbidity, and time on the ventilator as

compared to the reference group, 39 to 40 weeks of gestation (127). Interestingly, in the same analysis, those born before 37 weeks of gestation or after 40 weeks of gestation also had increased morbidity rates and longer ventilatory times (127). Furthermore, in the Pediatric Heart Network single ventricle trial, subanalysis showed that rates of preterm birth (16% vs. 12%, $p < 0.001$), low birth weight (18% vs. 8%, $p < 0.001$), and small for gestational age (22% vs. 10%, $p < 0.001$) were higher in those with single ventricle anatomy as compared to the general population (128).

There are many studies evaluating the subgroup of patients <2,500 g who have congenital heart disease. In one report (129), the mortality rate for closed procedures was 10.4% versus 5.4% for the comparison group. Similarly, the mortality rate for open heart procedures in those <2,500 g was 25.4% versus 10.5% for term counterparts. The actuarial survival rate at 10 years was 51%. Another study examined palliations versus complete biventricular repair in the same weight cutoff and noted that a higher mortality rate was seen in premature infants (vs. low birth weight) and in those who had undergone palliations (130). One study (131) showed that overall surgical mortality in those <2,500 g (either palliation or definitive repair) was 18%. Definitive repair was associated with better outcomes with 13% mortality versus 28% mortality in those who underwent palliative surgery. Medium-term follow-up indicated that survival was 87% in those with corrective surgery and 54% in the palliation group. Obviously, morbidity is higher in the entire low birth weight group compared to term infants. Statistical analysis showed that early outcome was independent of age, weight, prematurity, use of cardiopulmonary bypass, and type of intervention. The authors concluded that primary correction has an early survival benefit over palliation. These results were similarly noted in a series of 60 patients <2,500 g with 35 who had cardiopulmonary bypass (132). Overall results showed acute deaths being 15% and survival at 60 months to be 70% for the entire group. A recent study of 75 consecutive infants weighing <2,500 g who underwent surgical palliation with a heterogeneous set of heart anomalies including single ventricle anatomy and complex cyanotic congenital heart disease revealed a 90% overall 1 year survival and a 88% 5-year survival by Kaplan-Meier analysis (133). Patients in this cohort who had a genetic abnormality had a 28% overall mortality rate as compared to 5.4% in those without a chromosomal issue (133).

Similar conclusions have been made for the very low birth weight infant (<1,500 g). Complete repair has been advocated for these patients since delays for weight gain have been shown to be associated with no long-term benefit and increased preoperative morbidity. Additionally, complete surgical correction is preferred over prolonged medical management or other palliative procedures (134).

Aggressive surgical strategies for the low or very low birth weight neonate have prompted cardiac catheterization in the same group. A recent study compared those <1,500 g who had undergone catheterization in a case-control study with the comparison population weighing between 2 and 3 kg (135). In essence, success rates, complication rates, incidence of blood transfusions, and incidence of major complications were the same for each group. The procedures in the very low birth weight infant are rare, yet pose an impetus for equipment alterations and safety considerations in the catheterization lab for these patients (135). In the past, transcatheter closure of the PDA in low birth weight or preterm infants was felt to be technically challenging and was thus not considered a good option as compared to traditional surgical intervention (136). However, several contemporary reports of catheterization intervention with various devices to occlude the PDA in selected preterm infants have been published (137–142).

INTERDISCIPLINARY APPROACH

This unique patient population merits the same interdisciplinary approach provided to children and adults with congenital heart disease. A firm understanding of neonatal physiology and organ system development is imperative to assure the highest quality of care. The future of this field may involve an evolution of multiple services that may lead to specific neonatal cardiac services that will promote research and enhance care.

Dean B. Andropoulos ■ Anthony C. Chang

Pediatric cardiovascular intensive care has become increasingly organized as a subspecialty over the past decade, in response to the explosion of knowledge and research in the patient with critical cardiac disease, the increasing complexity of cardiac lesions and procedures to treat them, and the growing numbers of patients of a younger age requiring cardiac intensive care. An international subspecialty society, the Pediatric Cardiac Intensive Care Society, was organized in 2003 to address the issues facing practitioners (1). The consensus that critically ill pediatric patients with acquired or congenital heart disease (CHD) are best cared for in units or systems organized and designed for these patients and by practitioners with specialized training, expertise and skills in this area has dramatically changed the patient care paradigm. The pediatric cardiologist plays a central role in the critical care of these patients. This chapter reviews the organization of Pediatric Cardiac Intensive Care Unit (PCICU) services, as well as continuous quality improvement and family-centered care. Then, evaluation of cardiac output (CO) and treatment of low cardiac output syndrome (LCOS) are addressed. Next, major organ systems as they relate to cardiac intensive care are reviewed. Perioperative care for specific lesions and procedures is next presented. Finally, medical conditions in the PCICU and special considerations for the neonate and adult are reviewed.

ORGANIZATION OF CARDIAC INTENSIVE CARE SERVICES

Despite remarkable progress in the organization of PCICU services, there has been relatively little published information about the optimal delivery of care to this specialized patient population (2–4). Practitioners of the subspecialty may be pediatric cardiologists, pediatric intensivists, pediatric anesthesiologists, or pediatric cardiac surgeons. In a recent survey, 73% of North American and 59% of worldwide PCICUs involved care by pediatric intensivists (5). Specialized training in pediatric cardiac intensive care varies, from a 4th year of training following a standard pediatric cardiology or intensive care fellowship in the United States, to extra dedicated months of training during a pediatric intensive care fellowship, or pediatric cardiovascular anesthesiology fellowship. Many practitioners acquire significant training and experience in PCICU care after formal training is finished. Fellows who cover a PCICU can include those training in pediatric cardiology, intensive care, anesthesia, and congenital heart surgery. As of this writing, there is no formal specialized certificate or board certification in PCICU in the United States. Clearly, the physicians caring for PCICU patients optimally must have special interest, experience, and focus on this patient

population and spend a significant amount of their clinical time caring for them in order to maintain skills, knowledge, and expertise in this complex and rapidly changing field. The projected significant need for PCICU physicians, and the relatively small number of these physicians being trained, means that continued multidisciplinary support of PCICU programs is essential (2,6).

Similarly, the physical organization of PCICU beds varies considerably. In a recent survey of PCICUs in the United States and worldwide, 27 of 29 high-volume centers, defined as >300 open surgical cases per year, cared for patients in dedicated PCICUs. Smaller programs were more likely to care for pediatric cardiac intensive care patients in mixed Pediatric Intensive Care Units (PICUs) or adult cardiac surgical ICUs (5). Designs range from separate, dedicated PCICUs remote from the PICU, to the PCICU having separate beds but being adjacent or in close proximity to the PICU, to a mixed PICU/PCICU with cardiac patients dispersed throughout the unit. Other important design aspects considered optimal include close proximity to cardiac operating rooms (ORs) and catheterization laboratories to account for the frequent patient transfers back and forth for care, and the need for rapid response and frequent communication with the practitioners in these disciplines. Proximity to imaging modalities such as computed tomography and magnetic resonance imaging is highly desirable. Bed space considerations are very important, as PCICU patients often require space for echocardiography, nitric oxide (NO) delivery systems, extracorporeal support, and bedside surgical procedures. Ample space for the OR team, surgical lights, and provision for a sterile surgical field is highly desirable. In addition, space for family is increasingly planned in modern PCICU designs. A minimum standard for bed space per patient in PICUs is 250 square feet (23 m²), but in modern PCICU designs, up to 500 square feet are often planned (7). Bed spaces may be arranged as single room individual beds, as shared spaces divided by movable sliding glass partition doors, or as open-bay design for multiple patients. Careful consideration for visibility of beds and monitors should be made during design of the PCICU. Many PCICUs are designed with rectangular or square pods of 8 to 10 beds for maximum visibility and access. Adherence to local regulatory standards for windows, clean and dirty utility areas, isolation rooms, negative pressure rooms, and nutrition preparation areas is also very important.

Although PCICUs may vary in terms of the type of patients admitted, it is important for each unit to have a specified set of admission criteria. Some units may be limited to postsurgical cardiac patients, but increasingly, PCICUs admit both medical and surgical patients with critical cardiac disease requiring constant monitoring and access to medical, nursing, and ancillary expertise. This often includes the preoperative neonate, patients with severe medical cardiac disease, and even adults with CHD who have had cardiac surgery.

Multidisciplinary Team Approach to Pediatric Cardiac Intensive Care

One of the most important paradigm shifts in PCICU care is the recognition that multidisciplinary care beyond the traditional group of cardiologists, surgeons, intensivists, and anesthesiologists is increasingly important. Additional medical disciplines including adult CHD, neonatology, neurology, gastroenterology and nutrition, general surgery, pulmonology, genetics, nephrology, and others are vitally important to provide consultations and participate in multidisciplinary rounds. Nursing care deserves special emphasis, as the specialized skills and knowledge in PCICU care are critically important to establish and maintain. Nursing staffing ratios must be carefully planned, and nurse-to-patient ratios can vary from 1:3 for less ill, nonventilated patients, to 1:1 for less stable ventilated patients, to 2:1 for extracorporeal membrane oxygenation (ECMO) patients (5). In addition, as trainee duty hours and rotations are restricted by the U.S. Accreditation Council for Graduate Medical Education and other organizations, midlevel practitioners are increasingly employed in PCICUs, including pediatric nurse practitioners and physician's assistants. In some PCICU settings, pediatric hospitalists serve to augment manpower. Other crucial members of the multidisciplinary team (ideally dedicated and with special expertise in PCICU) include respiratory therapists, extracorporeal life support (ECLS) specialists, pharmacists, nutritionists, occupational and physical therapists, social workers, translators, and unit secretaries dedicated to the PCICU (3). Input is sought from all of these stakeholders in the patient's care by the attending PCICU physician, and all members of the team must be given the opportunity to contribute on rounds, and other formats for multidisciplinary collaboration. Multidisciplinary team planning for crises, including cardiopulmonary resuscitation (CPR) and ECMO, which includes simulation scenarios, is important to prepare for the actual events. The parent, patient, and family are also important members of the team (see below). This multidisciplinary approach, with the patient's best possible outcome as the foremost priority, helps eliminate traditional barriers such as "surgical versus medical," "physician versus nursing," and "parent versus caregiver." The director of the PCICU should be a dedicated physician leader who is a seasoned clinician possessing excellent skills in management, organization, and mentorship; these are essential qualities to maintain team cohesion and consistent excellent patient care (3). Managing diverse viewpoints from many disciplines with patience, and having consideration for all stakeholder contributions, are hallmarks of an effective leader.

Night and weekend physician coverage of the PCICU is an important concern, as these commonly unstable patients often are admitted off hours following long surgical procedures, or are transported from outside facilities. It is ideal to provide 24-hour in-hospital presence of an attending cardiac intensivist to assist in dealing with complex management decisions, new admissions, and procedures. This may not be possible in all hospitals; provisions for rapid call-in of the attending physician must be in place in this case. Ideally also, the on-call team of fellows, residents, and midlevel practitioners, as well as the attending physician, should have their duties limited to the PCICU.

Special patient populations being admitted to the PCICU in increasing numbers include low birth weight (LBW) neonates, and adults over the age of 18 years, who have critical cardiac disease. The LBW patients require consultation with neonatologists to optimize management, especially with regard to pulmonary management of immature lungs, feeding and nutrition, infectious issues, and multiple congenital anomalies other than the heart defect. The adult with CHD greatly benefits

from consultation with adult CHD specialists, who also assist in coordinating other adult consultants who may be needed such as neurologists and nephrologists. Another increasing patient group includes patients requiring ECLS, in the form of ECMO or ventricular assist devices (VADs). The complex problem of anticoagulation regimens to prevent thrombosis while not allowing excessive bleeding requires ready availability of consultants from hematology, or hematopathology services whose specialized knowledge of coagulation issues enhances care of these patients.

Relationship between the PCICU, the Cardiac OR, and the Catheterization Laboratory

An important principle of PCICU care is that the service should be delivered as a continuum of care well in advance of an intervention (3,5). This should begin with the presurgical or catheterization admission to the PCICU, surgical or catheterization planning conference, or even the prenatal multidisciplinary conference where the care and disposition of antenatally diagnosed CHD patients are discussed. Ideally, patients requiring intensive care are admitted preoperatively to the same unit, under care of the same team as they will have postoperatively to facilitate better knowledge of the patient's unique condition and communication with the surgeon, cardiac catheterization team, and family. Colocation of the PCICU near catheterization laboratories and cardiac ORs facilitates communication, rapid transport of very unstable patients, and proximity of skilled assistance during crises in the PCICU, ORs, or catheterization laboratory. The continuum-of-care principle also applies to immediate postoperative, or postcatheterization care, with clear hand-off communication from the procedural teams to the PCICU team and continuing of the support provided in the OR or catheterization laboratory.

Continuous Quality Improvement and Patient Safety in the CICU

Improving patient safety, reducing medical errors, and optimizing outcomes of care have been a priority of the US health care system since the landmark publications of the Institute of Medicine, "To Err is Human" in 1999 (8), and "Crossing the Quality Chasm" in 2001 (9). These issues are particularly important in the PCICU, where complex pathophysiology, invasive procedures, multiple caregivers, multiple physician orders and medications, and the unpredictable nature of events present a multitude of opportunities for errors, both active and latent, which may result in adverse events (10). A culture of patient safety involves change that begins with the PCICU leadership and affects everyone involved in PCICU care, including junior physicians, nurses, and ancillary personnel. Important principles identified to promote a safety culture in complex environments include leadership promoting a safety culture; process design based on human limitations that eliminates unnecessary variability; promoting team work and team functioning; proactive anticipation of unexpected events; and creation of a learning environment that empowers any personnel to report errors and to speak up when unsafe practices are encountered. Care handoffs, whether between nursing or physician shifts, on transfer from OR to PCICU, or transition to a new care team, are frequent sources of error and miscommunication. Protocols for face-to-face handoffs that include a checklist improve consistency of communication and prevent many avoidable errors (11). Communication in the PCICU environment is a key concern. One simple method unique to this environment

DIAGNOSIS

- 1) Hypoplastic left heart syndrome (mitral and aortic stenosis).
- 2) Norwood procedure with a 3.5 mm Blalock-Taussig (BT) shunt.
- 3) Right subclavian artery occlusion.
- 4) Right ventricular dysfunction.
- 5) Bidirectional Glenn
- 6) Poorly controlled atrial tachycardia.

Figure 20.1. Diagram posted on the bed of a patient in the PCICU for rapid identification of cardiac anatomy.

is to place a diagram of the cardiac anatomy of each patient, along with the recent surgical or catheterization procedure, on or near the bed, for easy visibility during an acute event (Fig. 20.1). Other programs with demonstrated effectiveness are central catheter insertion and maintenance “bundles” that include checklists for insertion that guarantee full sterile precautions during insertion, placement of a chlorhexidine disk at the catheter insertion site, regular dressing changes, and daily assessment of the need for the catheter. The PCICU has a particularly high rate of central line-associated blood stream infections (CLABSI), and coordinated efforts have resulted in dramatic reductions in these events by as much as 80% to 90% (12,13).

The electronic medical record (EMR) is increasingly utilized in PCICUs and will become a requirement in the United States in the coming years. The EMR can be an important factor in improving the quality of data recorded that can lead to improved patient outcomes. The EMR can be an important tool for legible, accessible documentation of physician admission and daily progress notes, as well as the electronic nursing PCICU flow sheet that documents not only bedside monitor data but all medications and nursing interventions. The ability to perform bedside echocardiography efficiently, and to review the images at the bedside, is important to optimize PCICU care. Computerized physician order entry can lead to more accurate and timely carrying out of orders, and decision support functions tied to hospital formulary can help avoid medication errors. Implementation of a complete EMR system is costly, and careful planning is needed to ensure the EMR interfaces well with all other electronic systems, such as picture archiving and communicating systems (PACS), and Cardiology databases that display echo and catheterization images. Ample numbers of computer workstations, including

mobile computer carts, are necessary to avoid delays in documentation or physician orders. Processes of care must be understood, and the transition to EMR should be carefully planned to avoid work-arounds that prevent full and effective implementation of the system (14,15).

Databases to measure quality and outcomes in the PCICU, both local internal databases, and national or international multicenter databases, are increasingly recognized as essential functions. It is crucial to have access to the PCICU's basic data, such as number of admissions, type of surgical or catheter procedure, diagnoses, demographics of admitted patients, severity of illness or complexity of surgical procedure, lengths of stay, days on mechanical ventilation, patients receiving mechanical support, and mortality and major morbidity rates. These data are used for internal quality improvement purposes, for comparison to outcomes from other PCICUs, and as the bases for research publications and presentations. Databases available for PCICUs include the Virtual PICU Database Cardiac Module (16), Society of Thoracic Surgeons' Congenital Heart Surgery Database (17), Congenital Cardiac Anesthesia Society Database (18), and IMPACT Registry for catheter interventions (19).

Family-Centered Care

Hospitalization in the PCICU for an intervention or illness, whether known in advance and planned, or emergent and unplanned, is a stressful and emotional experience for the patient, parents, and family. There has been considerable recent progress in involving the family as much as possible in their child's care, and where possible and developmentally appropriate, involving the child in his or her own care. PCICU routines that can involve the parents in the child's care, and reduce stress levels for both parent and patient include a liberal visitation policy that allows the parent to be at bedside with the child whenever possible (20). For times when the child is in surgery or the catheterization laboratory, or when the parent needs a break from the PCICU environment, having comfortable family waiting areas in close proximity to the PCICU is very desirable. Private conference rooms for discussions with the family, away from the unit, are another important feature to allow privacy during critical meetings. Some recent PCICU designs incorporate enough space into individual patient rooms to accommodate parent sleeping in the room. Allowing parents to be present on work rounds, to hear the presentation and discussion of their child's care, has become an important routine in many PCICUs that, if done sensitively, increases the flow of accurate information to the parent and reduces stress. In a recent survey of PCICU physicians and nurses, 77% responded that parents had a right to be present during work rounds, 57% felt parents should be allowed to be present during invasive procedures such as tracheal intubation and arterial and central line placement, and 75% would allow them to be present during CPR. Of these scenarios, parents wanted to be present about 65% of the time for work rounds, but only about 30% of the time for invasive procedures, or for CPR (21). Family-centered care may require a change of culture among the physicians and nurses in the PCICU, and there must be an adequate orientation of the family members as to policies and expectations. With the presence of so many families in the PCICU, strict policies about not disclosing medical information heard about other patients' conditions must be explained and enforced. Despite the occasional inconveniences, or changes in well-established routines, adopting family-centered care fully will result in greater parent and patient satisfaction, and help to reduce the stress, uncertainty, and other negative emotions associated with PCICU admission.

EVALUATION AND MANAGEMENT OF THE CARDIOVASCULAR SYSTEM

The frequent or continual assessment of CO and oxygen delivery, and ensuring that they are optimized, or at least that measures are being undertaken to do so, are the central tenets of cardiac intensive care. This section will review various methods that assess CO.

Physical Examination, Bedside, and Laboratory Data

Despite the availability of many technologically advanced methods, CO should always be assessed by inspection and physical examination in addition to monitoring data, and the invasive and noninvasive methods described below. Poor CO is often heralded by pale or mottled extremities, diminished peripheral pulses, delayed capillary refill (>2 to 3 s), increasing cyanosis, tachycardia, poor heart tones, diminished pulses, cool extremities, presence of third or fourth heart sounds, and evidence of hepatic and pulmonary congestion. Urine output is often decreased. Lethargy or irritability often accompanies low CO. Tachypnea, diaphoresis, and poor feeding are often present. Although these are simple principles, they should not be forgotten in the modern profusion of technology-based monitoring methods.

Routine continuous monitoring of physiologic variables in the PCICU including heart rate, electrocardiogram (ECG), arterial and central venous pressure waveforms, temperature, and end-tidal CO_2 (ETCO_2) can give important information about CO. These include the ECG displaying nonsinus rhythm, elevated filling pressures or lack of an "a" wave on atrial filling pressures, acute decrease in ETCO_2 with increased ETCO_2 to PaCO_2 gradient, blunted arterial waveform upstroke or excessive respiratory variation, and increased core-to-peripheral temperature gradient. Chest radiograph findings include cardiomegaly, pulmonary edema, or, alternately, a paucity of pulmonary vascular markings associated with inadequate pulmonary blood flow. Laboratory data include an increasing calculated base deficit or serum lactate, or persistent lactate above 2 mmol/L (22,23).

Echocardiography

Bedside echocardiography in the PCICU is a very important tool for assessment of CO during a given point in time. Whether formal echocardiogram with complete anatomic and functional assessment, with official interpretation or reporting by an echocardiographer (preferred), or a rapid assessment with portable echocardiography during a crisis, this tool is indispensable for evaluation of CO in the PCICU, yielding information not obtainable by other methods. Besides the obvious measurement of ventricular function by qualitative assessment, ejection fraction or quantitative assessment using shortening fraction, or myocardial performance index, many other important findings are made during low CO states. These include residual anatomic defects such as shunts, outflow tract obstruction, presence and degree of valvular regurgitation or stenosis, pericardial fluid or thrombus leading to a diagnosis of tamponade, assessment of right ventricular function, tricuspid regurgitation jet, and position of the interventricular septum to assess pulmonary hypertension (PH), and many others (24). If standard transthoracic views are not adequate, transesophageal echocardiography can be performed in the intubated, sedated patient. Bedside echocardiography is essential during the performance of balloon atrial septostomy (BAS) (25). Obtaining a bedside echocardiogram the morning after cardiac surgery is routine in many PCICUs. Bedside echocardiography is an excellent modality to define intracardiac anatomy, but extracardiac structures (systemic-pulmonary shunts, pulmonary veins, cavopulmonary anastomoses, aortic arch) are not as

reliably imaged by echocardiography and may require cardiac catheterization (see below).

Venous Oximetry

Measurement of true mixed venous oxygen saturation in the pulmonary artery (PA) of a patient with two ventricles and normal cardiac anatomy is rarely possible in the PCICU; much more useful is the measurement of oxygen saturation in the superior vena cava (SVC), used as a surrogate for mixed venous saturation (26). This technique is used during cardiac catheterization for calculation of CO using the Fick method. Many PCICU patients will have a catheter in the SVC for central venous access. A measured, not calculated, oxygen saturation, or ScvO_2 , can be an important trend monitor to assess CO, and oxygen delivery and consumption. This measurement can be made intermittently, or during changes in patient status, or in response to interventions.

Continuous monitoring of intravascular oxyhemoglobin saturation using reflectance catheters has been used in the umbilical artery, PA, and adult-sized central venous catheters for a number of years, but only recently have standard pediatric-sized 4 and 5 French, double and triple lumen central venous catheters become available for routine use to measure central venous oxygen saturation (ScvO_2) in pediatric patients. In several small studies of pediatric patients undergoing cardiac surgery, good correlation has been demonstrated between ScvO_2 as measured with the catheter, versus blood co-oximetry ($r^2 = 0.8$ – 0.9 , bias -0.03 to $+1.09\%$ with standard deviation 4% to 8%) (27,28). The advantage of this method is that it is continuous, many patients have SVC catheters in place, and the oximetry catheters are of the same diameter as standard central venous catheters. Although assessment of each patient must be individualized, ScvO_2 below 50% in patients with univentricular hearts is often associated with low CO and/or oxygen delivery. For example, in univentricular neonates after Stage I palliation for hypoplastic left heart syndrome (HLHS), low ScvO_2 was associated with death and greater frequency of increased need for ECMO. Goal-directed therapy targeting $\text{ScvO}_2 > 50\%$ is associated with high postoperative survival and low complication rate in this population (29).

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a noninvasive optical technique used to monitor brain and somatic tissue oxygenation. Most devices utilize 2 to 4 wavelengths of infrared light at 700 to 1000 nm, where oxygenated and deoxygenated hemoglobin have distinct absorption spectra (2–4). An oxygen saturation is derived using variants of the Beer-Lambert equation. This saturation is designated a regional oxygen saturation (rSO_2) and is a weighted average of the saturation in venous, arterial, and capillary beds in the light path. Since its now classic description in 1977 by Jobsis (30), this technology has been the subject of over 1000 publications, and because of its noninvasive, compact, portable nature, and potential to measure tissue oxygenation in the brain and other organ systems during surgery and critical illness, it is gaining more widespread clinical use.

In critical care medicine, cerebral NIRS has been used to monitor adequacy of cerebral oxygen delivery and as a surrogate for adequacy of global oxygen delivery in patients after cardiac surgery and in patients on ECMO or VADs (31,32). Changes in rSO_2 have a close correlation with changes in mixed venous saturation (SvO_2) in both single- and two-ventricle patients after congenital cardiac surgery (33,34).

NIRS can be used to measure tissue oxygenation in surgery and critical illness and because of its noninvasive continuous nature has intuitive appeal in conditions where low CO and other causes of shock would benefit from continuous monitoring. Somatic NIRS using a probe placed on the flank at T10-L2 has

been studied by Hoffman et al. (35) in a series of neonates after and during single-ventricle surgical palliation. In nine neonates undergoing cardiopulmonary bypass (CPB) with regional cerebral perfusion (RCP), mean cerebral rSO_2 pre-bypass was 65% and somatic rSO_2 was 59%. During RCP cerebral rSO_2 was 81% versus 41% somatic, signifying relative tissue hypoxia due to lack of perfusion to subdiaphragmatic organs. After CPB, cerebral rSO_2 decreased to 53%, but somatic rSO_2 increased to 76% (35). In 79 postoperative neonates undergoing Norwood Stage I palliation for HLHS, a cerebral–somatic rSO_2 difference of <10% significantly increased the risk for biochemical shock, mortality, or other complications (36). Mean somatic rSO_2 < 70% was associated with a significantly increased risk of prolonged ICU stay, shock, and other complications.

Somatic NIRS has also been used with a probe placed on the abdomen between the umbilicus and symphysis pubis to measure mesenteric rSO_2 in neonates and infants after cardiac surgery. In a study of 20 patients, Kaufman et al. (37) compared mesenteric NIRS and flank NIRS at T10–L2 to gastric pH measured by tonometry and lactate values. In 122 simultaneous measurements made in the first 48 hours after surgery, mesenteric rSO_2 correlated significantly with gastric pH ($r = 0.79$) and serum lactate ($r = 0.77$), SvO_2 ($r = 0.89$). These correlations were all better than those using flank NIRS. The authors concluded that mesenteric NIRS is a sensitive monitor of splanchnic tissue oxygenation and may have utility at managing these patients and improving outcomes. In addition, for infants undergoing biventricular repair, flank (renal) rSO_2 values below 50% for >2 hours in the immediate postoperative period were associated with higher peak creatinine levels, higher incidence of acute kidney injury, greater inotropic support, more days on mechanical ventilation, and higher serum lactate levels (38).

These studies lend credence to the idea that NIRS-directed targeted interventions could be utilized to improve oxy-

gen delivery to tissues and organs and potentially improve outcomes from surgery, anesthesia, and critical illness. To date, there is a lack of such published studies, but more are anticipated given the nature of this modality.

Thermodilution Cardiac Output

Percutaneous PA catheterization has a limited role in the PICU for several reasons. The small size of many patients precludes placement of adequately sized sheaths and catheters, and many patients in whom PA catheter monitoring would be desirable have intracardiac shunting, invalidating results of standard thermodilution CO measurements and confusing mixed venous oxygen saturation (SvO_2) measurements. In addition, right-sided intracardiac surgery makes PA catheterization undesirable. Thus, when pulmonary artery pressure (PAP) or SvO_2 monitoring is indicated, transthoracic PA lines are the most common method used in congenital heart surgery. The availability of continuous central venous oxygen saturation catheters (see below), and the perception that the risk:benefit ratio for PA catheter placement is most often unfavorable, limit indications for this technique (39–42).

Cardiac index may be measured by standard thermodilution methods, with care taken to input the correct calculation constant into the monitor software according to the catheter size and length, and volume and temperature of injectate. The average of three consecutive injections made in rapid succession at the same point in the respiratory cycle, that is, expiration, will optimize conditions to achieve an accurate measurement during steady-state conditions. Vascular resistances and stroke volume can also be calculated, using the formulae shown in Table 20.1 (41,42).

Hemodynamic data represent only a portion of the information available from an oximetric PA catheter. The

TABLE 20.1

Hemodynamic Formulae for Pulmonary Artery Catheter Monitoring

Formula	Normal Values		
	Adult	Infant	Child
$CI = \frac{CO}{BSA}$	2.8–4.2 L/min/m ²	2–4	3–4
$SVI = \frac{SV}{BSA}$	30–65 mL/beat/m ²	40–75	40–70
$LVSWI = \frac{1.36(MAP - PCWP) \times SVI}{100}$	45–60 g · m/m ²	20–40	30–50
$RVSWI = \frac{1.36(PAP - CVP) \times SI}{100}$	5–10 g · m/m ²	5–11	5–10
$SVRI = \frac{(MAP - CVP) \times 80}{CI}$	1500–2400 dyne · s · cm ⁻⁵ m ²	900–1200	1300–1800
$PVRI = \frac{(PAP - PCWP) \times 80}{CI}$	250–400 dyne · s · cm ⁻⁵ m ²	<200	<200

CI, cardiac index; CO, thermodilution cardiac output; BSA, body surface area; SV, stroke volume; SVI, stroke volume index; LVSWI, left ventricular stroke work index; RVSWI, right ventricular stroke work index; SVRI, systemic vascular resistance index; PVRI, pulmonary vascular resistance index.

TABLE 20.2 Oxygen Delivery and Consumption Formulae

Formula	Normal Values		
	Adult	Infant	Child
Arterial O ₂ content: $CaO_2 = (1.39 \times Hb \times SaO_2) + (0.0031 \times PaO_2)$	18–20 mL/dL	15–18	16–18
Mixed venous O ₂ content: $CvO_2 = 1.39 \times Hb \times SvO_2 + 0.0031 \times PvO_2$	13–16 mL/dL	11–14	12–14
Arteriovenous O ₂ content difference: $avDO_2 = CaO_2 - CvO_2$	4–5.5 mL/dL	4–7	4–6
Pulmonary capillary O ₂ content: $CcO_2 = 1.39 \times Hb \times ScO_2 + 0.0031 \times PcO_2$	19–21 mL/dL	16–19	17–19
Pulmonary shunt fraction: $Q_s / Q_t = 100 \cdot (CcO_2 - CaO_2) / (CcO_2 - CvO_2)$	2%–8%	2–8	2–8
O ₂ delivery index: $DO_2I = 10 \cdot CO \cdot CaO_2 / BSA$	450–640 mL/min/m ²	450–750	450–700
O ₂ consumption index: $VO_2I = 10 \cdot CO \cdot (CaO_2 - CvO_2)$	85–170 mL/min/m ²	150–200	140–190

Hb, hemoglobin; SaO₂, measured arterial oxygen saturation; PaO₂, partial pressure of oxygen in arterial blood; SvO₂, measured mixed venous oxygen saturation; PvO₂, partial pressure of oxygen in mixed venous blood; ScO₂, measured pulmonary capillary oxygen saturation; PcO₂, partial pressure of oxygen in pulmonary capillary blood; Q_s, pulmonary shunt blood flow; Q_t, total pulmonary blood flow.

other half consists of oxygen delivery and consumption measurements and calculations, which may also be used to guide therapy in the critically ill patient who has LCOS (41,42) (Table 20.2). They require either measurement of mixed venous and systemic arterial saturations from blood samples from the tip of the PA catheter and arterial line (measured by co-oximetry, not calculated), or substitution of these values with SvO₂ from the oximetric catheter (a valid assumption if properly calibrated), and pulse oximeter value instead of measured systemic saturation. There are data from adult and pediatric critical care literature suggesting that the ability to increase and maximize both oxygen delivery and consumption may improve outcome, and that these are predictors of survival from critical illness, including postoperative cardiac surgery (43–46).

Lithium Dilution and Pulse Contour Analysis Cardiac Output

Because traditional percutaneous, balloon-tipped PA catheterization is limited in small children and those with intracardiac shunting several other recent methods to measure CO and oxygen delivery in patients with CHD have been applied. Lithium dilution cardiac output (LiDCO) uses a standard central line in the SVC or even a peripheral IV catheter, and a special femoral artery catheter equipped with a lithium-detecting electrode. A dilute solution of

lithium chloride is injected into the vein, and arterial blood is withdrawn into the lithium electrode. The cardiac index is related to the area under the curve of the change of lithium concentration. This method has been demonstrated to have reasonable correlation with thermodilution CO in children after congenital heart surgery. In a study of 48 measurements in 17 patients 2.6 to 34 kg, correlation between LiDCO and thermodilution CO was good ($r^2 = 0.96$), mean bias was -0.1 ± 0.31 L/min (47).

Transpulmonary thermodilution CO uses a similar principle as LiDCO, with temperature as the indicator instead of lithium concentration. Cold saline is injected into a central venous catheter, and via a thermistor placed in a femoral artery, a time temperature curve is derived, which correlates reasonably well with standard thermodilution CO as measured by a standard PA catheter (48). Lithium and any thermodilution method are limited to patients without any intracardiac shunting, significantly restricting their use in patients with CHD.

Yet another newer method is pulse contour analysis of the arterial waveform (PiCCO), which relates the contour and area under the curve to the stroke volume, thus the CO. This continuous method is periodically calibrated using transpulmonary thermodilution CO as described above (again making the method invalid in patients with intracardiac shunting), and demonstrate good correlation with transpulmonary thermodilution in a recent study of 24 postoperative pediatric cardiac patients ($r^2 = 0.86$, mean bias:

$0.05 \pm 0.4 \text{ L/min/m}^2$), and in pediatric patients undergoing diagnostic catheterization after cardiac transplantation (49,50). A recent comprehensive review of publications of this method in children and in animal models of pediatric disease, showed agreement that the stroke volume and CO derived with pulse contour analysis are generally accurate and precise, and may be a useful adjunct for measurement of CO in critically ill children (51).

Table 20.3 summarizes physical examination findings and other data associated with low CO.

PREVENTION AND MANAGEMENT OF LOW CARDIAC OUTPUT SYNDROME

Determinants of Cardiac Output and Oxygen Delivery

Besides the unique factors discussed earlier that alter hemodynamic management in patients with CHD, it is important to recognize that alterations of preload, afterload,

TABLE 20.3 Clinical Findings in Low Cardiac Output State

Category	Parameter	Finding/Data
Physical examination		
	Peripheral perfusion	Cool or mottled extremities Diminished peripheral pulses Delayed capillary refill
	Respiratory status	Tachypnea, increased work of breathing, grunting, flaring, retractions
	Cardiac examination	S3 or S4, diminished heart tones, tachycardia or bradycardia
	Other physical examination	Diaphoresis, hepatomegaly, jugular venous distension, increasing cyanosis
	Mental status	Lethargy or irritability
Monitor data		
	Arterial waveform	Diminished pulse pressure, decreased upslope, hypotension, increased variation with respiration
	Atrial filling pressures	Significantly elevated or decreased; lack of "a" wave
	ECG	Nonsinus rhythm, tachycardia, bradycardia, ST-segment depression or elevation, lack of HR variability
	End-tidal CO ₂	Decrease in ETCO ₂ , large end-tidal to arterial CO ₂ difference
	Temperature	Increased core-to-periphery temperature gradient (>5°C core to toe)
	Mixed venous (PA) or central venous (SVC) oxygen saturation	Low SvO ₂ or ScvO ₂ < 50%
	Near-infrared spectroscopy regional oxygen saturation	Low cerebral rSO ₂ < 50%, low somatic (renal) rSO ₂ < 10% above cerebral rSO ₂
Laboratory and radiographic data		
	Serum lactate	Increasing, or persistently elevated over 2 mmol/L
	Calculated base deficit	Increasing or >5 mEq/L
	BNP	Elevated above 100 pg/mL and increasing
	Troponin-I	Elevated above 0.15 ng/mL and increasing
	Chest radiograph	Cardiomegaly, pulmonary edema, or paucity of lung vascular markings
	Renal function	Elevated BUN and creatinine Poor urine output < 0.5 mL/kg/h
Echocardiography		
	LV ejection fraction or shortening fraction; dilated LV	Decreased (EF < 50% or SF < 35%)
Calculated cardiac index		
	Thermodilution, lithium dilution, pulse contour analysis, echocardiographic by VTI method	<2.0 L/min/m ²

S3,S4, third and fourth heart sounds; ETCO₂, end-tidal carbon dioxide; PA, pulmonary artery; SVC, superior vena cava; SvO₂, mixed venous oxygen saturation; ScvO₂, central venous oxygen saturation; rSO₂, regional oxygen saturation; BUN, blood urea nitrogen; EF, ejection fraction; SF, shortening fraction; VTI, velocity time integral method.

Figure 20.2. Determinants of cardiac output and oxygen delivery.

contractility, and heart rate are four cornerstones that affect CO before and after surgical correction of congenital cardiac disease (Fig. 20.2). In addition, diastolic dysfunction is common in patients with CHD, and measures to improve ventricular compliance are important. The oxygen-carrying capacity of blood is improved by increasing the hemoglobin concentration. Each of these factors should be adjusted for the specific congenital cardiac lesion and the cardiovascular physiology that is associated with the lesion. Figure 20.3 details expected changes in ventricular pressure–volume, and

Starling relationships with manipulation of preload, afterload, contractility, and lusitropy.

Pharmacologic Therapy for Congenital Heart Disease

The goal of drug therapy in an acute setting should be to optimize CO and oxygen delivery; improve perfusion pressure to vital organs such as brain, heart, and kidneys; and maintain an optimal balance between systemic and pulmonary blood flows with an appropriate level of oxygenation. High levels of inotropic and vasoactive infusions in the first 48 hours postoperatively for infants under 6 months of age are associated with poor outcomes including need for mechanical circulatory support, prolonged ventilation, preserved neurologic injury, renal failure, long ICU stays, and death (52). Therefore, it is important to understand the actions of pharmacologic agents and to use them judiciously at the lowest effective doses.

Drugs that may be used in the acute hemodynamic management of patients can be categorized as belonging to one of the following functional classes:

1. Inotropes (epinephrine, dopamine, dobutamine, milrinone, calcium)
2. Chronotropes (isoproterenol)
3. Vasoconstrictors (norepinephrine, phenylephrine, vasopressin, terlipressin)
4. Vasodilators (nitroglycerin, nitroprusside, prostaglandins, NO, nicardipine, fenoldopam)
5. Beta adrenergic antagonists (esmolol)
6. Newer cardiotoxic and vasoactive agents (levosimendan, nesiritide)

The cardiac intensivist must keep in mind that the indications for and doses of these drugs in an individual patient are highly variable. Tables 20.4 and 20.5 summarize the effects and recommended dosages for these drugs. Effects such as age, disease state, and adrenergic receptor up- or down-regulation necessitate frequent titration of drugs to effect.

Preload Recruitment

Figure 20.3. Changes in pressure volume and Starling relationships with manipulations of preload (A), diastolic compliance (lusitropy) (B), contractility (inotropic state) (C), and afterload (D). Point A represents baseline end-diastolic volume on the pressure–volume loop on the left of each panel, and baseline stroke volume on the Starling curve on the left of each panel. SV, stroke volume. (A) Effect of increasing preload. With administration of intravascular volume, end-diastolic volume and stroke volume are augmented significantly from point A to point B. However, diastolic compliance is nonlinear, and increases in stroke volume are progressively less with more intravascular volume administration from points B to C, and C to D. At high end-diastolic volumes and pressures, pulmonary capillary leak ensues resulting in pulmonary edema and pleural effusions.

Improve Diastolic Function (Positive Lusitropy)

Increase Contractility (Positive Inotropy)

Afterload Reduction

Figure 20.3. (Continued) (B) Effect of improving diastolic function. Enhanced ventricular relaxation and compliance result in an increased end-diastolic volume at the same pressure, point A versus B. This results in an increased stroke volume at the same atrial pressure. Slowing heart rate, or instituting an agent such as milrinone can improve lusitropy. (C) Effect of increased contractility. Increases in the slopes of the pressure-volume loops from points A, to B, to C, represent progressively increased inotropic states. Increased contractility results in a higher stroke volume ejected at the same left atrial pressures. (D) Effect of afterload reduction. At normal inotropic state, represented by the changes from point A to point B, lowering afterload allows the heart to eject to a lower systolic pressure, resulting in a higher stroke volume. With a decreased baseline inotropic state, represented by the changes from point C to point D, the increase in stroke volume with afterload reduction is much greater for a comparable change in afterload. Heart failure patients and neonates are particularly sensitive to changes in afterload.

TABLE 20.4 Inotropic Drugs

Drug	Dose	Receptors	Inotropy	HR	SVR	PVR	Renal Vascular resistance
Epinephrine	0.02–0.2 $\mu\text{g/kg/min}$	$\beta_1, \beta_2 > \alpha_1$ $\alpha_1 > \beta_1, \beta_2$	\uparrow	\uparrow	$\leftrightarrow, \downarrow$	$\leftrightarrow, \downarrow$	\downarrow

Inotropes

EPINEPHRINE

Epinephrine is an endogenous catecholamine that is secreted by the adrenal glands and has strong α - and β -adrenergic receptor activation. This action on both types of adrenergic receptors leads to the complexity of response in different organs and tissue beds. The response of exogenously administered epinephrine depends on the ratio of α to β receptors in the individual tissue beds as well as to the dose of epinephrine given. At lower doses ($<0.05 \mu\text{g/kg/min}$), epinephrine causes a moderate increase in systolic blood pressure that is mainly due to the increased ventricular contraction (53). Activation of the β_2 receptors in the vasculature of the skeletal muscles usually leads to a decrease in the systemic vascular resistance (SVR) and the diastolic pressure. As the dose is progressively increased, more prominent peripheral vasoconstriction is seen due to the activation of the α receptors in other vascular beds (54). Renal blood flow is consistently decreased as vascular resistance in all segments of the renal vasculature increases (55). Epinephrine is often used as a strong inotrope for support of the failing myocardium. Epinephrine's action on the predominant β_1 receptors in the heart leads to an increase in contractility and heart rate. Higher doses will lead to a decrease in the refractory period of the atrioventricular (AV) node and an increase in the automaticity of the myocardium, which may predispose to the development of atrial or ventricular arrhythmias.

During CPR, epinephrine is the vasopressor of choice since it has profound α -adrenergic stimulation that aids in maintaining the cerebral and coronary perfusion pressure during cardiovascular collapse (56). The American Heart Association-recommended dose of epinephrine in children for bradycardia, asystolic or pulseless arrest is 0.01 mg/kg intravenously, repeated at 3- to 5-minute intervals. Higher doses of epinephrine are no longer recommended (57,58).

Epinephrine is used as an infusion primarily in the dose range from 0.02 to $0.2 \mu\text{g/kg/min}$, although doses up to $0.5 \mu\text{g/kg/min}$ or higher are occasionally used in the short term for acute severe low CO in situations such as weaning from bypass, or during ECMO cannulation or emergency institution of bypass. Prolonged exposure to high doses of epinephrine, that is, 0.1 to $0.2 \mu\text{g/kg/min}$ or higher for more than several hours, may cause myocardial necrosis in infants, and strong consideration should be given for mechanical circulatory support in this instance (59).

DOPAMINE

Dopamine is a naturally occurring catecholamine that is an immediate precursor of norepinephrine. Most of the functions of endogenously excreted dopamine are as a central neurotransmitter, though it has been found in the peripheral circulation as well. The cardiovascular effects of exogenously administered dopamine are due to the activation of a variety of receptors that have different affinity for the drug (60). At a lower dose ($<5 \mu\text{g/kg/min}$), the primary receptors that are activated are the dopaminergic-1 (DA-1) receptors present in the renal, mesenteric, and coronary vascular beds. Infusion of low-dose dopamine can lead to an increase in renal blood flow and an increase in glomerular filtration rate (GFR) (61). However, "renal dose" dopamine has not been demonstrated to have direct beneficial effects in improving renal function (62). As the dose of the drug is increased, stimulation of the β_1 receptors in the myocardium has inotropic and chronotropic effects (63). At these doses, dopamine causes an increase in CO, decrease in pulmonary capillary wedge pressure, and usually a decrease in SVR with only slight changes in blood pressure. The increase in heart rate is much less than for isoproterenol. Total peripheral resistance is usually unchanged with low or

intermediate doses of dopamine, due to vasodilatory action of dopamine on regional vascular beds. At higher doses ($>10 \mu\text{g/kg/min}$), more α_1 receptors are activated leading to a more intense peripheral vasoconstriction and an increase in vascular resistance. Dopamine causes release of norepinephrine from nerve endings; this also adds to its pharmacologic effect of adrenergic stimulation.

The volume of distribution and the clearance of dopamine are highly variable, underscoring the principle of titrating this drug to effect in the individual patient (64). Dopamine in the dose range 5 to $15 \mu\text{g/kg/min}$ is commonly used as an inotropic support to assist in the weaning from CPB, and in the early postoperative period. In recent years, some practitioners have avoided dopamine because of its role as a neurotransmitter, which can cross the blood brain barrier and is known to suppress pituitary function, particularly thyroid releasing hormone, in infants and children (65). These potential adverse effects are not seen with other natural or synthetic catecholamines (66).

DOBUTAMINE

A synthetic congener of dopamine, dobutamine's pharmacologic actions are due to its activation of α - and β -adrenergic receptors. Dobutamine has not been shown to have any effect on the DA receptors or the release of norepinephrine from nerve endings. The primary action of dobutamine is on β_1 receptors with only a small effect on β_2 or α_1 receptors. This action causes increased inotropy and chronotropy. CO is markedly enhanced and the left-sided filling pressures are decreased. Total peripheral resistance is unchanged or may decrease with the use of dobutamine. This effect may be especially beneficial in treating patients with ventricular dysfunction.

There is little direct increase in renal blood flow as is seen with dopamine. Dobutamine given in doses ranging from 5 to $15 \mu\text{g/kg/min}$ has been shown to be effective in improving depressed cardiac index after CPB in children with CHD (67). Comparison with newer inotropic drugs such as milrinone demonstrates similar improvements in stroke volume but a more profound decrease in left ventricular filling pressures and vascular resistance with the phosphodiesterase inhibitors (68). Increased heart rate is more prominent with dobutamine than with milrinone. At equivalent inotropic doses, dobutamine enhances the automaticity of the sinoatrial (SA) node to a much less extent than isoproterenol (69). Higher doses of dobutamine ($>15 \mu\text{g/kg/min}$) can predispose to the development of atrial or ventricular arrhythmias. Despite the fact that dobutamine will increase CO in neonates by increasing stroke volume, heart rate, and CO, it is frequently used to stress the myocardium, and will increase myocardial oxygen consumption, and produce diastolic dysfunction in some patients with repaired CHD (70,71).

MILRINONE

Milrinone is a bipyridine derivative that induces vasodilation and exerts a positive inotropic effect by inhibiting phosphodiesterase III. This leads to the accumulation of cyclic adenosine monophosphate (cAMP), independent of adrenergic receptor stimulation (72). The increase in cAMP in cardiac myocytes improves systolic and diastolic function by altering calcium influx (73), and by altering uptake and binding of calcium to myofilaments; whereas in vascular smooth muscle, accumulation of cAMP predominantly affects the removal of calcium across sarcolemma and therefore causes vasodilation. The decrease in SVR allows phosphodiesterase inhibitors to increase CO and oxygen delivery without increasing myocardial work and oxygen demand. Because of the dual effects on the inotropic state of the heart and the vascular resistance, milrinone has been used extensively in the treatment of congestive heart failure, PH, and postoperative low CO.

Milrinone has been shown to be an effective inotrope in adults as well as in children with CHD (74,75). Peripheral vasodilation also ensues as a result of vascular smooth muscle relaxation. Chang et al. reported that milrinone (loading 50 $\mu\text{g/kg}$ followed by an infusion of 0.5 $\mu\text{g/kg/min}$), when administered to neonates with low CO after cardiac surgery, lowered filling pressures, systemic and pulmonary vascular resistances (PVRs) (>25%), and improved cardiac index (from 2.1 to 3.1 L/min/m²) (76). Bailey et al. (77) found an increase in CO of 18% after milrinone therapy in 20 children undergoing corrective surgery for congenital cardiac defects. Milrinone also improves diastolic function. Hypotension and reflex tachycardia may result as side effects of milrinone therapy. Mehra et al. (78) reported a 4% incidence of thrombocytopenia in 71 patients who received long-term intravenous milrinone therapy (>3 days). Milrinone is primarily excreted by the kidneys, and higher bolus doses (50 to 75 $\mu\text{g/kg}$) may show prolonged hemodynamic effects in patients with impaired renal function. Serum half-life was found to be 0.8 hours in patients with congestive heart failure (79). Milrinone has also been suggested to have a higher volume of distribution and a faster clearance in infants and children as compared to adults (79). The dose recommended for milrinone therapy in patients with normal renal function is a bolus of 50 $\mu\text{g/kg}$ followed by an infusion of 0.25 to 0.75 $\mu\text{g/kg/min}$. Hypotension seen with a loading dose may be avoided by reducing or eliminating the loading dose and simply beginning the infusion, recognizing that therapeutic plasma levels will not be achieved for several hours.

In recent years, milrinone has gained widespread use in CICUs and is one of the few regimens that have been studied in a prospective, randomized, double-blind, controlled manner. In 227 infants and children undergoing cardiac surgery with bypass, high-dose milrinone (75 $\mu\text{g/kg}$ loading dose after bypass, followed by 0.75 $\mu\text{g/kg/min}$ infusion) reduced the incidence of LCOS by 55% compared to placebo or low-dose milrinone (25 $\mu\text{g/kg}$ load and 0.25 $\mu\text{g/kg/min}$) (80). In a pharmacokinetic study of 16 neonates undergoing Norwood Stage I palliation, a loading dose of 100 $\mu\text{g/kg}$ into the bypass circuit at the start of rewarming provided therapeutic plasma concentrations, but an infusion of 0.5 $\mu\text{g/kg/min}$ caused a significant increase in plasma milrinone concentration over the first 12 hours; impaired renal function was thought to be the cause, and neonates may require lower doses of 0.2 $\mu\text{g/kg/min}$ (81).

CALCIUM

The calcium ion is an integral part of the excitation-contraction coupling and impulse generation in myocardial cells and is a major determinant of vascular smooth muscle tone. Particularly in neonates, where the sarcoplasmic reticulum is not well developed, and the sequestration and release of calcium is thus inefficient, an adequate ionized calcium concentration is important to optimize myocardial contractility. Administration of calcium in the form of calcium chloride or calcium gluconate helps improve the inotropic function of the heart in the presence of hypocalcemia (82). Calcium functions primarily as a vasoconstrictor when the serum ionized calcium levels are normal. Routine administration of calcium salts upon termination of CPB is a subject of debate. The incidence of hypocalcemia during CPB is relatively high, but the ionized calcium levels usually are corrected to normal levels as weaning from CPB is attempted (83); therefore, calcium administration may not be necessary for most patients. Moreover, increasing evidence suggests that elevated intracellular calcium levels are associated with cell death and injury during ischemia and reperfusion injury (84). Murdoch et al. reported an increase in the SVRI (885 to 1,070 dyne/cm⁵/m²) and a decrease in CI (4.44 to 3.85 L/min/m²)

after administration of 10 mg/kg of CaCl₂ in 12 children following cardiac surgery (85). Rapid administration of calcium can slow the heart rate transiently, and it should be used cautiously in patients who are taking digoxin as it may precipitate digoxin toxicity.

Calcium administration is not recommended in severe bradycardia or asystole unless severe hypocalcemia or hyperkalemia coexists or if the arrest is secondary to calcium channel antagonist drugs (57,58).

A higher and more predictable amount of elemental calcium is available from the intravenous administration of calcium chloride than calcium gluconate or gluceptate (86). Because the neonatal myocardial sarcoplasmic reticulum is not well organized, and release and reuptake of Ca²⁺ is not efficient, some anesthesiologists administer a CaCl₂ infusion of 10 mg/kg/h to neonates after CPB, especially when they received citrated blood products for postcardiotomy bleeding. However, a recent retrospective review of infants <1 year of age demonstrated that mortality after cardiac surgery with bypass was correlated with higher Ca²⁺ supplementation, suggesting that this agent should be used only with documented hypocalcemia with associated myocardial dysfunction, or in neonates receiving significant amounts of citrated blood products, and should be discontinued as soon as possible (87).

Chronotropes

ISOPROTERENOL

Isoproterenol is a potent nonselective β -adrenergic agonist with only very minimal actions on α receptors. Due to its vasodilatory β_2 stimulatory actions as well as lack of α -receptor stimulation, isoproterenol leads to lowering of peripheral vascular resistance (53,88). Its vasodilatory actions may be seen in renal, mesenteric, and pulmonary vascular beds. CO is increased in patients with heart failure as a result of the increased inotropy and chronotropy in the face of diminished SVR. An intravenous infusion of isoproterenol has more chronotropic than inotropic effect, as opposed to dopamine or dobutamine. Myocardial oxygen demands are greatly exacerbated by isoproterenol, and this may exacerbate or induce ischemia (89). Higher doses of isoproterenol can be arrhythmogenic and may induce ventricular tachycardia (VT) or ventricular fibrillation (VF). This agent is contraindicated in dynamic obstruction of the right or left outflow tracts.

Isoproterenol has been shown to cause less hyperglycemia than epinephrine, since insulin secretion is stimulated by strong β -adrenergic stimulation. The drug has been shown to be effective in increasing the heart rate in patients with severe bradycardia or a heart block (57,58). This chronotropic effect of isoproterenol remains the principal use of the drug, and it is often used in electrophysiologic studies to increase heart rate and incite atrial and ventricular arrhythmias. Its principal use in the cardiac ICU is in the denervated heart immediately after heart transplant, or in cases of complete AV block. Isoproterenol is generally not used as a first-line drug in the management of myocardial dysfunction or in the treatment of heart failure. The dose for isoproterenol infusion ranges from 0.01 to 0.2 $\mu\text{g/kg/min}$.

Vasoconstrictors

NOREPINEPHRINE

Norepinephrine is an endogenous catecholamine that is primarily released by the postganglionic adrenergic nerve endings. Besides being a major source of epinephrine, the adrenal medulla also contains norepinephrine in a smaller fraction (10% to 20%). The actions of norepinephrine are very similar to epinephrine on the heart with strong stimulation of the β_1 receptors and increase in myocardial contractility (55). There is a substantial difference in the peripheral action of the two drugs (53) accounting for the variation in their clinical

use. Norepinephrine is a potent α_1 agonist at all doses with minimal effects on the vasodilatory β_2 receptors (53). As a result, even low doses of norepinephrine lead to an increase in the systolic and diastolic blood pressure. SVR is increased as a result of the vasoconstriction of most peripheral vascular beds. CO is usually decreased or unchanged, depending upon the increase in total peripheral resistance. Heart rate may be slowed as a result of reflex increase in vagal tone, or may occasionally increase if the β_1 effects predominate in an individual patient. Both of the endogenous catecholamines, epinephrine and norepinephrine, can cause hyperglycemia with prolonged infusions (90). Norepinephrine usually causes these effects at much higher doses than epinephrine.

Norepinephrine functions as a strong vasoconstrictor and is useful in the clinical situation of decreased SVR; however, it is used infrequently in infants and children. Dose range of norepinephrine infusion varies from 0.02 to 0.2 $\mu\text{g/kg/min}$. It is effective in raising SVR in cases of profound vasodilatory shock unresponsive to high doses of dopamine or dobutamine, such as from sepsis in neonates (91).

PHENYLEPHRINE

Phenylephrine is a pure peripheral α_1 -receptor agonist used as a bolus or an infusion where low systemic blood pressure must be treated acutely. The pure α effects often result in reflex slowing of the heart rate, although this is not as pronounced in young infants. Its principal use in CHD is to acutely raise SVR when either ventricle is compromised by outflow obstruction, for example, tetralogy of Fallot (TOF) with low SVR leading to increased right-to-left intracardiac shunting and cyanosis during a "tet Spell," (92) and hypertrophic cardiomyopathy (93) or other left-sided lesions where the gradient across the obstruction is increased by low SVR. It is also useful where an acute increase in SVR is needed to improve oxygenation, that is, partially obstructed systemic-to-pulmonary shunt, or single-ventricle patient with pulmonic stenosis. Infusions can be used when frequent boluses are necessary, such as in the TOF patient whose tetralogy spell is continuous before transfer to the OR. Phenylephrine is very effective at increasing the blood pressure, but its principle adverse effect is vasoconstriction of peripheral tissue beds, including skeletal muscle, skin, renal, and mesenteric. This vasoconstriction may be intense, and theoretically may compromise end-organ blood flow and function, leading many practitioners to limit its use to extreme situations. Extravasation of phenylephrine into the skin and subcutaneous tissues may lead to ischemia, necrosis, and tissue loss. A reflex slowing of heart rate may be observed, and vigilance is necessary with large phenylephrine doses. Bolus dosing of phenylephrine is 0.5 to 5 $\mu\text{g/kg}$ or higher, and infusion dosing ranges from 0.02 to 0.3 $\mu\text{g/kg/min}$ should be administered through a central venous catheter if possible.

VASOPRESSIN

Vasopressin is a neurogenic polypeptide produced by the paraventricular nucleus of the mid-brain in response to low blood pressure and is secreted by the posterior lobe of the pituitary. Vasopressin produces intense vasoconstriction and an antidiuretic effect. Vasopressin exerts these effects via V1 (vasoconstriction) and V2 receptors (antidiuresis). In the past, the most common use of vasopressin was to treat gastrointestinal bleeding. More recently, vasopressin has been used as an alternative to epinephrine in the acute resuscitation; however, the superiority of vasopressin over epinephrine for this indication is not clear. A theoretical advantage of vasopressin is that it does not rely on adrenergic receptors, which may be down-regulated in chronically elevated catecholamine states. In conditions of metabolic acidosis, signal transmission via adrenergic receptors is also ineffective. Some conditions producing low blood pressure (i.e., septic shock) are associated with low plasma vasopressin concentration, suggesting inappropriately low vasopressin

secretion. In some of these patients, hypersensitivity to the administration of vasopressin has been described, possibly due to up-regulation of vasopressin receptors, and is in agreement with studies showing rapid desensitization to vasopressin (94).

Rosenzweig et al. reported their experience with use of vasopressin in moribund pediatric patients after cardiac surgery (95). These patients were classified as unresponsive to standard vasopressors, and the dosage of vasopressin varied from 0.018 to 0.12 U/kg/h. These doses of vasopressin produced an average increase in systolic blood pressure of 22 mm Hg (65 to 87 mm Hg). Measured plasma vasopressin levels were low in the three patients. Patients who had low blood pressure and poor cardiac function before the initiation of vasopressin therapy died. Vasopressin is particularly useful in cases of low SVR induced by excessive α -adrenergic blockade, such as with phenoxybenzamine or phentolamine (96). There are now a number of case series of vasopressin, and its synthetic analog, terlipressin, being used to treat refractory vasodilatory shock in pediatric patients with cardiogenic and septic etiologies (97,98). Vasopressin doses range from 0.01 to a maximum of 0.05 U/kg/h, and should be weaned and discontinued as soon as possible. Hyponatremia is often seen with vasopressin infusions of several days' duration, and serum sodium should be measured at least daily.

Vasodilators

NITROGLYCERIN

Nitroglycerin produces vasodilation by releasing NO. The release of NO from nitroglycerin, unlike that of some other NO donors, is enzymatically mediated. Nitroglycerin is frequently referred to as a venodilator while sodium nitroprusside (SNP) is thought of as a preferential dilator of arteries, although these differences are difficult to demonstrate. The major indications for the use of nitroglycerin are myocardial ischemia, systemic hypertension, PH, volume overload, congestive heart failure, and pulmonary edema. Venodilation associated with nitroglycerin therapy leads to a decrease in venous return. The decrease in preload leads to a lowering of the left ventricular end-diastolic volume and pressure, and therefore decreased wall stress. The net effect is usually an improvement in the ratio of myocardial oxygen demand to delivery. Nitroglycerin also dilates both diseased and normal coronary arteries (99). Hypotension and reflex tachycardia are the potentially undesirable side effects. Nitroglycerin is used in the cardiac surgical patients for the treatment of systemic or pulmonary hypertension, and to decrease filling pressure and improve cardiac index. In a study including 20 pediatric patients with CHD, of whom 14 had preoperative PH, nitroglycerin ($>2 \mu\text{g/kg/min}$) reduced both systemic and PVRs (100). Improved cardiac index was seen only with higher doses. The authors suggested that the effect of the drug on the systemic and pulmonary arteries and on capacitance vessels was dose related. In lower doses ($<2 \mu\text{g/kg/min}$), nitroglycerin mainly produced venodilation, as evidenced by an increased requirement of volume to maintain constant right and left atrial pressures. The usual doses of intravenous nitroglycerin infusion are 0.5 to 5 $\mu\text{g/kg/min}$.

SODIUM NITROPRUSSIDE

The hypotensive properties of SNP were described in the late 1800s; however, the drug was not approved for clinical use until 1974. Frequently, nitroprusside is incorrectly referred to as a "direct, preferential arterial vasodilator." Nitroprusside dilates both arteries and veins by releasing NO in an interaction with tissue compounds containing sulfhydryl groups. The released NO activates soluble guanyl cyclase that increases cGMP. Nitroprusside is most commonly used to control blood pressure in hypertensive patients, and to decrease SVR thereby improving forward flow in patients with poor LV function or

regurgitant lesions (mitral or aortic regurgitation). Because of its short half-life, SNP allows precise control of blood pressure and SVR. In patients with diminished myocardial function, CO is increased from an increased stroke volume as a result of decreased aortic impedance. Despite significant reductions in SVR, the blood pressure decrease is usually modest since an increase in CO compensates for the decrease in SVR. The drop in blood pressure is more dramatic in patients with pre-existing hypovolemia or obstructive cardiac lesions. In patients with hypertrophic cardiomyopathy SNP may increase outflow obstruction, and patients with aortic or mitral stenosis may not be able to compensate with an increase in CO, resulting in profound hypotension. SNP has been used for early postoperative afterload reduction after Norwood Stage I palliation to lower SVR and decrease $Q_p:Q_s$, with excellent early hemodynamics and high early survival rate (101).

One of the dangers associated with the use of nitroprusside is toxicity from the formation of cyanide. Cyanide a by-product of SNP metabolism, is taken up by red cells and inactivated predominantly in the liver by reacting with thiosulfate. This reaction is catalyzed by the enzyme rhodanese, and patients with liver failure are more susceptible to cyanide toxicity. If cyanide toxicity occurs, SNP should be stopped immediately, and after confirmation of diagnosis, the patient should be treated with 3% sodium nitrate followed by administration of sodium thiosulfate. SNP should be used cautiously in patients with renal failure since they may have difficulty metabolizing the thiocyanate produced during breakdown of SNP. In a retrospective review of 63 children receiving SNP after cardiac surgery to control blood pressure, or to lower SVR for hemodynamic purposes, 11% of patients experienced an elevated cyanide concentration. Mean SNP dose was 2.8 $\mu\text{g/kg/min}$ in those patients with elevated cyanide levels, and 1.1 $\mu\text{g/kg/min}$ for those without elevated levels with an increased risk of elevated cyanide levels starting at 1.8 $\mu\text{g/kg/min}$ (102).

The starting dose of SNP is 0.5 to 1 $\mu\text{g/kg/min}$, and the dose can be titrated up to 5 $\mu\text{g/kg/min}$. The high doses pose greater risk for toxicity, so doses exceeding 3 $\mu\text{g/kg/min}$ should not be administered for longer than several hours. Sodium thiosulfate can be added to the infusion to eliminate cyanide, but alternative methods of hypertension treatment should be instituted. In a multicenter study of 118 infants and children receiving esmolol for blood pressure control on admission to the ICU after coarctation repair via thoracotomy, only 15% to 20% of neonates, 50% of patients aged 1 to 24 months, and 80% of patients aged 2 to 6 years were treated with SNP for blood pressure control. The median maximal SNP dose was 3 $\mu\text{g/kg/min}$, and there was no mortality, neurologic complication, or significant acidosis (103).

PROSTAGLANDINS

Prostaglandins such as PGE_1 and PGI_2 are the main metabolites of the arachidonic acid pathway. In the vascular tissues, they are predominantly generated and subsequently released by the endothelium to bind to specific receptors on the underlying smooth muscle cells. This leads to the activation of adenylate cyclase and an increase in cAMP levels, which lowers intracellular Ca^{2+} and produces vascular smooth muscle relaxation.

PGE_1 is used to relax smooth muscle and maintain the patency of the ductus arteriosus in neonates whose systemic or pulmonary circulations are dependent on ductal patency. PGE_1 , when administered to 27 neonates in whom pulmonary or systemic blood flow was entirely or significantly dependent upon ductal patency, led to an improvement in hypoxemia and acidemia, as well as ductus dilation (104). It has been demonstrated to maintain ductal patency for as long as 2 months (105) and to reopen a recently closed ductus. Preoperative drug therapy with PGE_1 has lowered the mortality

and allowed planned surgeries, rather than desperate attempts at emergency palliation, which was frequently the case in the past. Hypotension, apnea, hyperpyrexia, and jitteriness, side effects of PGE_1 therapy, occur in 20% to 40% of patients at higher doses (0.05 to 0.1 $\mu\text{g/kg/min}$), but they are usually reversible upon lowering the dose or discontinuation of the drug.

Besides management of neonatal CHD, PGE_1 has been used to treat PH secondary to mitral valve disease (106), after congenital cardiac surgery (107) and after heart transplantation (108). There has been only limited research conducted in the use of inhaled PGE_1 .

PGI_2 or prostacyclin (epoprostenol) is a relatively recent addition to the drug therapy for the management of pulmonary vascular disease. Even though PGI_2 is probably the most selective pulmonary vasodilator of all the currently available intravenous drugs, administration of PGI_2 via this route will also lower systemic arterial pressure. PGI_2 is spontaneously hydrolyzed to 6-keto-prostaglandin $\text{F}_{1\alpha}$ with a half-life of 1 to 3 minutes. The relatively selective effect on lowering PVR is due to rapid inactivation in the pulmonary vasculature bed during a single circulation time. Intravenous infusions of PGI_2 (epoprostenol) have been shown to be useful in decreasing the PVR in patients with primary PH and after cardiac surgery in neonates (109). Due to its short half-life, aerosolized PGI_2 , like NO, can selectively dilate pulmonary vessels with minimal effects on the systemic arterial pressure. Several anecdotal reports and a few small clinical studies suggest that inhaled PGI_2 can reduce elevated PAPs and PVR. Schulze-Neick et al. reported inhaled PGI_2 and NO to have similar advantageous effects on reducing PVR in patients with CHD after cardiac surgery (110). Another study demonstrated reduction of PAPs and improvement in the right ventricular function following inhaled PGI_2 therapy with bolus dosing (2.5, 5, 10 μg) in nine patients undergoing cardiac surgery including heart transplantation (111). The optimal dosing of epoprostenol remains undefined, and dosing of inhaled PGI_2 ranging from 1 to 50 ng/kg/min has been shown to be efficacious (112). This agent has also been demonstrated to lower elevated PAP and PVR in infants after congenital heart surgery with bypass (113).

SILDENAFIL

Sildenafil is a phosphodiesterase-5 inhibitor, which, in its intravenous form, appears to be a selective and highly effective pulmonary vasodilator in a piglet model of meconium aspiration with severe PH (114). Sildenafil has been shown in case reports to ameliorate the effects of NO withdrawal in a patient after cardiac surgery with persistent PH (115). In doses of 0.5 to 2.0 mg/kg given NG, sildenafil was effective at lowering mean PAP in infants after AV septal defect repairs (116).

INHALED NITRIC OXIDE

A ubiquitous compound in the human body, NO is produced as a result of the conversion of the amino acid arginine to citrulline, a reaction that is facilitated by the enzyme nitric oxide synthase (NOS). NO, being a very small and lipophilic molecule, diffuses into the underlying smooth muscle cells producing an increase in intracellular cGMP levels and subsequent vasodilation (117). NO, when delivered via the inhaled route, readily crosses the alveolar-capillary membrane leading to pulmonary vasodilation and a decrease in PVR. High-affinity binding and immediate inactivation of inhaled nitric oxide (iNO) activity by hemoglobin limits the action of the drug to the pulmonary circulation. iNO therapy has been shown to be useful in the treatment of PH, which is frequently seen in CHD (117,118). PH in patients with CHD is multifactorial, due to chronic hypoxemia or due to chronic elevation of pulmonary blood flow and/or pulmonary venous pressures. PVR

is also increased immediately after CPB due to the endothelial dysfunction. iNO is ideally suited in selectively reducing PVR during this critical period (118). The pulmonary vascular selectivity of iNO may be especially useful in reducing the right ventricular afterload in patients undergoing heart transplant, where the donor hearts may not be accustomed to high PVR of that is usually seen in these patients (119). Several investigators have reported the use of iNO in the preoperative period as a test of reversibility of PVR and in predicting post-CPB PH, as well as using the preoperative evaluation to predict the use of the drug in the immediate post-CPB period (117,120–122).

Others have reported the benefit of iNO in improving oxygenation, likely by improving pulmonary blood flow and ventilation–perfusion balance in congenital cardiac surgery patients (123). Even though iNO has been shown to be effective in a variety of congenital heart lesions, it may not be helpful in reducing PVR in all patients. In a double-blind study, the combination of milrinone 0.5 $\mu\text{g/kg/min}$ and NO 30 ppm was more effective at lowering PAP than either agent alone (124). The nonresponders are usually those who have long-standing PH and extensive remodeling of the pulmonary vasculature. NO also has not been shown to improve postoperative outcome, the cost is prohibitive at several thousand dollars per day of use, the delivery system setup is complex, as is transport with NO, and there are toxicity issues (see below). All of these issues suggest that NO should only be used as a last resort in a patient with known or suspected severe PH resulting in low CO (in two-ventricle patients), or severe desaturation in single-ventricle patients after systemic arterial or venous to PA shunts.

NO can be administered using a face mask in a spontaneously ventilating patient, or added to the inspiratory limb of the breathing circuit in a mechanically ventilated patient. The most commonly used dose range is 10 to 20 ppm, though a decrease in PVR has been demonstrated with doses as low as 2 to 5 ppm. Side effects of iNO at these doses are minimal, even with prolonged therapy.

A novel approach is to administer IV L-citrulline, an amino acid precursor of NO, as a potential therapy to increase NO concentrations and prevent pulmonary hypertensive crises in susceptible patients. Initial phase I and phase II trials have demonstrated predictable pharmacokinetics and no safety issues so far with this approach (125). Abrupt withdrawal of NO or rapid reductions in drug dosage may lead to rebound PH (126). The binding of NO to hemoglobin gives rise to methemoglobin (127), and methemoglobin levels should be routinely monitored especially with prolonged therapy.

Nitrogen dioxide is also formed as a by-product of NO administration, and its levels should be maintained below 5 ppm. Nitrogen dioxide in high concentrations can lead to injury of the lungs (117).

FENOLDOPAM

Fenoldopam is a selective dopamine-1 receptor agonist with moderate affinity for α_2 receptors. Despite its binding to α_2 receptors, fenoldopam has no significant sedative effect. Fenoldopam administration produces dramatic vasodilation of the peripheral vasculature including renal, mesenteric, coronary, and skeletal muscle. The main indication for the use of fenoldopam is in the treatment of hypertensive emergencies and postoperative hypertension (128–130). The theoretical advantage of use of fenoldopam is that it maintains renal perfusion while decreasing blood pressure. This is especially important in patients with decreased renal function, since in rapid drop in blood pressure these patients may lead to decreased renal blood flow, decreased GFR, and even acute renal insufficiency. During prolonged infusion of fenoldopam, there is development of tolerance with a half-life (predicted loss of 50% effectiveness of the drug) of 60 hours, without

a prolonged pharmacodynamic effect or rebound hypertension upon discontinuation of fenoldopam. In a retrospective study of 25 postoperative cardiac neonates with inadequate urine output despite conventional diuretic therapy, fenoldopam increased urine output by 50% and had minimal effect on hemodynamics (131).

NICARDIPINE

Nicardipine is a dihydropyridine calcium channel antagonist that relaxes vascular smooth muscle by inhibiting calcium entry, resulting in decreased systolic, mean, and diastolic blood pressure and SVR (132). Its negative inotropic effects are minimal, and compensatory tachycardia is less than for other direct vasodilators, that is, nitroprusside. It is effective for antihypertensive therapy in postoperative cardiac surgical patients with adequate LV function. Nicardipine has been used successfully for postcoarctectomy hypertension after repair via thoracotomy in children, with significant decreases in mean arterial pressure and minimal increase in heart rate (133). Despite its lack of negative inotropic effect, this agent should not be used in patients with decreased systemic ventricular function, and only should be used with great caution in young infants.

Beta Adrenergic Antagonists

β -Blockers, like angiotensin-converting enzyme (ACE) inhibitors, are more beneficial in the management of chronic heart failure where they have been shown to improve the functional status in both pediatric and adult CHD (134,135). This effect is due to the modulation of the endogenous neurohumoral system. Several studies have demonstrated downregulation of β adrenoceptors in chronic heart failure as a result of elevated sympathetic tone (136,137). Therapy with β -blockers such as propranolol, metoprolol, and carvedilol increase the number of myocardial β adrenoceptors and improve myocardial function in heart failure secondary to CHD (138,139). Responsiveness to catecholamines may be preserved in these patients during the perioperative period as a result of β -blocker therapy. Besides their use in the management of chronic heart failure, these medications have several uses in the acute hemodynamic management of patients with CHD. By reducing the effects of increased sympathetic tone on the right ventricular infundibulum in TOF, β -blockers are effective in the treatment of cyanotic spells (140). Also, a decrease in heart rate allows a longer diastolic filling time and improved preload. The use of esmolol, a short-acting β_1 selective antagonist, is well suited for the hemodynamic management of TOF in the perioperative setting (141). Esmolol in doses of 100 to 700 $\mu\text{g/kg/min}$ has also been successfully used to control postoperative hypertension after repair of aortic coarctation in children (103,142). Labetalol, a combined α - and β -adrenergic receptor blocker with 1:7 α : β blocking effect, is a frequent choice for intermittent IV dosing, during transition from continuous infusion β -blockade to oral therapy. Dosing at 0.1 to 0.2 mg/kg given every 1 to 4 hours is often effective.

Newer Cardiotonic and Vasoactive Agents

Currently, there exists limited scientific literature regarding the use of some new vasoactive drugs in patients with CHD, though a few of them have been well researched in other patient groups. A brief description of some of these newer agents is as follows:

LEVOSIMENDAN

Levosimendan is a positive inotrope and vasodilator. Most other positive inotropes work through stimulation of

adrenergic receptors and increase intracellular calcium that may be already elevated in the failing heart. Unlike these drugs, levosimendan works by causing conformational changes in the myofilaments making them more sensitive to intracellular calcium. The vasodilation produced is mediated by opening of potassium channels. Although drug is not approved for routine clinical use in the United States, there are extensive clinical studies involving large number of patients with end-stage cardiac failure demonstrating that levosimendan is both safe and effective in providing symptomatic relief. Levosimendan was also more effective in decreasing PA wedge pressure and increasing CO (143). Experience with the use of levosimendan in the perioperative period is limited. In a prospective randomized placebo-controlled trial in patients undergoing cardiac surgery, levosimendan given before separation from CPB enhanced cardiac performance, decreased SVR, increased myocardial oxygen consumption, and significantly decreased blood pressure, occasionally leading to hypotension (144). The hypotension was responsive to volume administration and vasoconstrictors were not needed. In 15 children with acute heart failure, levosimendan in doses of 6 to 12 $\mu\text{g/kg}$ load and 0.05 to 0.1 $\mu\text{g/kg/min}$ improved ejection fraction in all while allowing a reduction in dobutamine dose, with other hemodynamics unchanged (145). Despite exhibiting the expected hemodynamic effects, the drug has shown little or no effect on survival in adult patients with heart failure; thus, the drug has not been further developed for use in the United States.

NESIRITIDE (B-NATRIURETIC PEPTIDE)

Nesiritide is a human recombinant form of B-type natriuretic peptide (BNP) that is identical to and has actions that are similar to the endogenous BNP. Human BNP stimulates increases in intracellular cGMP in vascular endothelial cells and smooth muscles. Elevated cGMP levels with nesiritide therapy lead to venodilation and arteriodilation. Nesiritide has natriuretic, diuretic, and vasodilatory properties. Currently, the primary use of nesiritide is for treatment of acute decompensated heart failure where it produces dose-dependent reductions in the pulmonary capillary wedge pressure PCWP and systemic arterial pressure. In addition, vasodilation occurs without a change in heart rate and is associated with increases in stroke volume and CO. In a randomized controlled trial involving 489 subjects, nesiritide, when given as a bolus dose of 2 $\mu\text{g/kg}$ and followed by an infusion at 0.01 to 0.03 $\mu\text{g/kg/min}$, was more effective in lowering PCWP as compared to nitroglycerin (146). In another randomized controlled trial that included 103 patients with heart failure and systolic dysfunction, nesiritide was reported to decrease PCWP by up to 39%. This was accomplished by lowering the right atrial pressure (RAP) and SVR, along with a significant improvement in cardiac index (147). Colucci et al. (148) reported that nesiritide was as effective as standard drug therapies (dobutamine, milrinone, dopamine, or nitroglycerin) in treating heart failure. The renal hemodynamic effects of nesiritide (BNP) appear to be that of arteriolar vasoconstriction, which would likely augment GFR and filtration fraction in the setting of compromised renal perfusion. Additionally, BNP leads to increased urinary sodium excretion and fractional excretion of sodium (FENA) (149). Mild diuretic effect of nesiritide therapy has been reported in a few clinical trials (149,150). In a limited pediatric experience of 17 patients after cardiac surgery, a loading dose of 1 $\mu\text{g/kg}$ was administered on bypass, and then an infusion of 0.1 then 0.2 $\mu\text{g/kg/min}$ was continued. There was a 7% decrease in mean arterial pressure with no adverse effects (151). Use of this agent has been limited in the pediatric population, likely because multiple controlled adult trials have not demonstrated any survival benefit with this agent.

Mechanical Support

Patients who are receiving high-dose inotropic support, considered by many cardiac intensivists to be epinephrine, 0.1 to 0.2 $\mu\text{g/kg/min}$ (or its equivalent) for more than 2 to 4 hours and maintain only marginal CO must be considered for institution of mechanical support in the form of ECMO or VADs. Mechanical support is ideally instituted proactively, rather than after a cardiac arrest or onset of multiorgan failure. (See Chapter 21 for complete discussion of mechanical support therapies.)

ARRHYTHMIAS

Maintenance of normal sinus rhythm, or at least AV synchrony by temporary or permanent pacing, is a goal in every CICU patient. However, arrhythmias are a constant threat, and the intensivist must be ever vigilant to this problem when hemodynamic status is not optimal. This section will summarize the major acute classes of arrhythmia in the CICU; the reader is referred to Chapter 18 for a more extensive discussion.

Etiology and Incidence

In the CICU, postsurgical changes are among the most common causes of arrhythmia, secondary to surgical resection or manipulation of ventricular or atrial tissue. Numerous additional nonsurgical causes of arrhythmia are seen in CICU patients, and the total incidence of arrhythmia is 15% to 30% of CICU admissions (152,153). Junctional ectopic tachycardia (JET), affecting 2% to 5% of postsurgical patients (154), can necessitate mechanical support and can be fatal if not treated effectively. Patients most at risk are infants undergoing ventricular muscle resection, that is, in TOF repairs. This arrhythmia is characterized by impulses arising at or near the AV node, with a discharge rate faster than the atrial rate, loss of AV synchrony, and ventricular rates of 140 to 220 bpm with hypotension and poor CO. Other common arrhythmias include supraventricular tachycardias: atrial tachycardias and AV reentrant nodal tachycardias. These may be caused by intra-atrial interventions including suture lines in the atrium, BAS, or atrial cannulation. SA node injury from SVC cannulation may lead to sinus bradycardia or low atrial rhythm. Ventricular arrhythmias, including isolated premature ventricular contractions (PVCs), multifocal PVCs, VT, and VF, may be seen secondary to myocardial ischemia from aortic crossclamping or acquired coronary artery anatomic obstruction. Second- or third-degree AV block may be seen after surgical manipulation or sutures in the area of the bundle of His, particularly after perimembranous ventricular septal defect VSD repair or subaortic resection. Right bundle branch block is common after right ventricular surgery; left bundle branch block is rare but may be seen in some patients after left ventricular outflow tract surgery.

Sinus bradycardia may be seen after cardiac surgery with SA node injury, hypothermia, or hypoxemia. Sinus tachycardia may be seen with hyperthermia, excessive circulating catecholamines from exogenous (inotropes) or endogenous (inadequate analgesia or uncompensated heart failure) sources, and may significantly impair ventricular filling and ejection times.

Myocardial disease, whether from acute myocarditis, or cardiomyopathy from ischemic or a variety of other causes, may cause any of the above noted arrhythmias. Chronic arrhythmogenic substrates, that is, significant atrial enlargement causing atrial fibrillation, previous lateral tunnel Fontan circulation causing atrioventricular nodal reentrant tachycardia or intra-atrial re-entrant tachycardia (IART) previous Mustard or Senning repairs causing IART-inherited sodium channelopathies causing Long QT syndrome and ventricular

arrhythmias, are other etiologies of arrhythmias observed in CICU patients with hemodynamic compromise.

Diagnosis

Standard 5-lead ECG configuration (right arm, left arm, right leg, left leg, V lead over ventricular apex) for beat-to-beat continuous monitoring of ECG in the CICU is an important modality for arrhythmia diagnosis in every patient. Multilead display allows 8 leads to be displayed simultaneously on the bedside monitor for rapid diagnosis especially during hemodynamic compromise. The capability to electronically archive ECG waveforms, not merely heart rate, is important to retrospectively assess periods of hemodynamic compromise. Standard 12-lead ECG with extended rhythm strip recording in lead II and other leads is important to obtain as soon as possible for diagnosis of arrhythmia. Atrial electrograms, obtained with right and left arm leads connected to temporary atrial pacing wires placed during surgery, are very important tools for diagnosing tachycardias. Information available from implanted pacemakers and defibrillators provides crucial data not obtainable by other bedside means. Assessment of intra-atrial pressure waveforms provides important clues as to whether AV synchrony is preserved in tachycardia when the displayed ECG is ambiguous, as is often the case (Fig. 20.4). Loss of distinct A and V waves is an important sign of supraventricular tachycardia with retrograde conduction to the atrium. In junctional tachycardia, the A waves are not at all synchronized with the V waves. Bedside echocardiography, whether transthoracic or transesophageal, can also allow assessment of AV synchrony, atrial fibrillation, and other features sometimes not discernible by standard ECG methods. Finally, in the case of an open sternum, direct observation of the heart can also assist in the diagnosis of arrhythmia. Consultation from electrophysiology service experts is also highly desirable, particularly in questionable or complex cases.

Prevention and Treatment

Among the most common causes of arrhythmia in the CICU are electrolyte disturbances, particularly hypokalemia for atrial arrhythmias, commonly seen after diuretic use. Maintaining serum potassium values in the 3.5- to 5-mEq/L range is the normal goal for prevention, and IV potassium boluses of 0.5 to 1 mEq/kg over 1 hour are often necessary in the acute setting. Normal serum magnesium levels are an impor-

Figure 20.4. ECG demonstrating normal sinus rhythm the first third of the panel, with onset of supraventricular tachycardia. Note the arterial pressure tracing with a 12 to 15 torr decrease in systolic pressure, and the loss of the A wave on the central venous pressure tracing, with the appearance of large V waves with a systolic pressure increase from 10 to 16 mm Hg.

tant goal to prevent and treat ventricular arrhythmias and JET (155), and normal serum calcium and sodium levels are also desirable. Low serum pH, below 7.25 to 7.30, resulting in myocardial acidosis, promotes arrhythmia risk, particularly ventricular. Correcting acidosis with sodium bicarbonate or increasing minute ventilation are effective.

Excessive circulating catecholamines may contribute to JET, supraventricular tachycardias, ventricular arrhythmias, and sinus tachycardia with undesirable hemodynamic effects. Avoiding unnecessarily high doses of β -adrenergic agonists such as epinephrine and dopamine will decrease risk of such arrhythmias. Other pharmacologic agents such as pancuronium, with its vagolytic effects, or sedation with ketamine, may also contribute. Withdrawal from β -blockade given preoperatively for arrhythmias, prevention of right ventricular outflow tract (RVOT) spasm, or heart failure, is a frequent cause of relative catecholamine excess at the receptor level. Amiodarone is an effective treatment for JET (156). Temperature control is important to decrease the rate of firing of abnormal foci, most particularly JET. Maintaining normothermia is an important preventive measure, and actively cooling the patient to 34°C to 35°C is a cornerstone of JET treatment. Hypothermia is a cause of sinus bradycardia, particularly important in the neonate.

Pharmacologic treatment of acute arrhythmias in the CICU is restricted to a few effective agents. Atrial arrhythmias, including SVT, AVRNT, atrial fibrillation, and atrial flutter, may be treated with *procainamide* loading dose and infusion; effectiveness is variable but this agent can be discontinued with a reasonably short half-life so that other agents, that is, amiodarone can be used. *Amiodarone* load, 5 mg/kg IV over 15 to 30 minutes, can be repeated up to a total loading dose of 15 mg/kg, and is very effective for all atrial arrhythmias. The half-life of this agent is very long; excessive levels or interaction with procainamide may cause refractory ventricular arrhythmias. Rapid amiodarone administration to neonates, or to other very unstable patients, can result in cardiovascular collapse from hypotension due to its acute α -receptor blocking effects. Pretreatment with calcium chloride may prevent this potential disaster. Symptomatic reentrant atrial arrhythmias can be pharmacologically converted with *adenosine*, 50 to 200 μ g/kg pushed IV, which interrupts AV node conduction for up to 5 to 10 seconds (which itself can be problematic). Ectopic supraventricular arrhythmias, that is, atrial ectopic tachycardia and JET, will not respond to adenosine. *Vera-pamil*, the calcium channel-blocking agent, *must not* be used in infants and young children due to its acute effects on myocardial contractility. *Esmolol* infusion is often used in the acute setting and may be very effective, both in controlling the rate response and in suppressing ectopic atrial foci.

In the CICU setting, most cases of symptomatic atrial arrhythmias are treated with synchronized cardioversion, with multifunctional cardioversion/defibrillation/external pacing pads placed on anterior right chest and apex. A current of 0.5 to 1 J/kg is delivered. Sedation and analgesia will be required. If not effective, a second attempt is made, doubling the energy. Repeated failure to convert to sinus rhythm is very unusual; serum electrolytes, pH, and intrinsic myocardial disease are usual causes.

First-line treatment for ventricular arrhythmias often includes lidocaine, 1 to 2 mg/kg loading dose, and 20 to 50 μ g/kg/min. Amiodarone is effective for treating ventricular arrhythmias, again with attention to its acute vasodilating effects in infants, and interactions with other drugs, especially procainamide. For perfusing VT, cardioversion with 1 to 2 J/kg is effective, and for pulseless VT or VF, chest compressions along with immediate defibrillation using 2 to 5 J/kg are necessary. In the case of intractable arrhythmias with severe hemodynamic compromise, ECMO or VAD support may be necessary, until the arrhythmia can be controlled medically, or by ablation in the OR or catheterization laboratory.

TABLE 20.6 Drug Therapy of Acute Hemodynamically Significant Arrhythmias in the CICU

Drug	Dose	Indications	Comments
Adenosine	100 µg/kg rapid bolus, double if ineffective, max 300 µg/kg	SVT	May cause sinus pauses, bradycardia, AV block
Amiodarone	Load 5 mg/kg over 30–60 min; may repeat × 2; infusion 15–20 mg/kg/24 h	Atrial tachycardia, flutter, and fibrillation; JET; VT and VF	May cause sinus bradycardia, AV block, hypotension, drug interactions with procainamide and β-blockers
Atropine	10–20 µg/kg	Sinus bradycardia; Sinus bradycardia	
Epinephrine	1–5 µg/kg	Sinus bradycardia; AV block	
Esmolol	250–500 µg/kg load over 1–2 min; 50–500 µg/kg/min infusion	Sinus tachycardia; atrial and ventricular tachyarrhythmias	May cause negative inotropy, bradycardia, sinus pauses, AV block
Isoproterenol	0.01–0.03 µg/kg/min	Sinus bradycardia in denervated heart; complete AV block	β ₂ effects may decrease diastolic BP
Lidocaine	1–2 mg/kg load over 1 min; may repeat; infusion 20–50 µg/kg/min	PVCs, VT, VF	Toxicity from hepatic/renal failure
Magnesium sulfate	25–50 mg/kg load over 30 min	VT (Torsade de pointes), prevention of JET	May cause muscle weakness, sedation
Procainamide	10–15 mg/kg load over 30–45 min; infusion 20–40 µg/kg/min	Atrial tachycardia; JET; VT	Monitor procainamide and <i>N</i> -acetylprocainamide levels; may cause hypotension; synergistic adverse effects with amiodarone

SVT, supraventricular tachycardia; AV, atrioventricular; JET, junctional ectopic tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation; PVC, premature ventricular contraction.

Temporary pacing is frequently necessary in the CICU following cardiac surgery, and improves CO in most instances (157). Where there are arrhythmias in the OR, or high risk for arrhythmias exists based on patient history or surgical procedure, the surgeon should place temporary pacing wires at least on the right atrial appendage. Ventricular pacing wires are also placed, along with a ground lead on the skin, for any suspicion or actual disturbance in AV node conduction. Indications for pacing the atrium include sinus bradycardia and junctional rhythms including JET, where AV node conduction is still intact. In cases of actual or suspected risk for AV node or His bundle conduction disturbance, both A and V wires are used. For complete AV block, if no pacing wires are available, pharmacologic treatment with direct-acting β-adrenergic agents such as isoproterenol or epinephrine are used. Temporary external pacing with multifunctional pads is initiated during a crisis when no other means are available. More secure methods are then initiated, such as a transvenous pacing catheter, or emergency sternotomy or subxiphoid incision to place temporary pacing wires. Temporary pacemaker wire thresholds for capture ideally should be tested in the OR, and should be low, that is, 1 to 2 mV for atrial leads, and 2 to 4 mV for ventricular leads. After establishing thresholds, output should be adjusted to equal two times the threshold to establish a margin of safety. Continuous use of temporary wires over a period of days will result in increased thresholds due to damage to the myocardium from the electrical current. If thresholds increase, new temporary wires, or a means of permanent epicardial or transvenous pacing, must be considered. Pacemaker settings must reflect appropriate AV interval and refractory periods for the heart rate of the patient. In addition, in the OR setting pacing is often asynchronous, that is, dual chamber paced, no chamber sensed, no chamber inhibited (DOO); this must be converted to demand, or dual

chamber paced, dual chamber sensed, dual chamber inhibited (DDD) pacing, due to the danger of uncoordinated R on T pacing leading to ventricular fibrillation. Pacemaker thresholds should be checked daily, and pacemaker need should be assessed at least daily. The underlying cardiac rhythm is determined by disconnecting the pacemaker. In the case of surgically induced complete heart block, if there is no recovery after 7 to 10 days, it is highly likely that the condition is permanent, and plans for a permanent pacemaker must be made. Tables 20.6 and 20.7 list the treatment modalities for the most frequent symptomatic arrhythmias encountered in the CICU (158).

PULMONARY HYPERTENSION

PH is commonly encountered in the CICU, and complicates a variety of surgical and medical patients. A high index of suspicion for PH is important to recognize and consider this problem for patients not progressing well in their CICU course. (For a complete discussion of PH, see Chapters 66 and 67.) This section focuses on PH in the acute CICU setting.

Etiologies

In the modern era, the incidence and severity of PH in infants with long-standing left-to-right shunts from lesions such as VSD or AVSD is much lower than in the past, because of early complete correction strategies, now routinely at 2 to 4 months of age. These infants, particularly those with Trisomy 21, may have significant PH, particularly in the immediate postoperative period, when the inflammatory response from bypass,

TABLE 20.7 Pacing/Cardioversion/Defibrillation of Acute Hemodynamically Significant Arrhythmias in the CICU

Treatment	Dose	Indications	Comments
Atrial overdrive pacing	Rate 10%–20% faster than SVT rate for up to 15 s	SVT	
Atrial pacing with temporary wires	Desired rate for optimal hemodynamics	Sinus bradycardia, junctional bradycardia; JET	Output double the capture threshold
AV sequential pacing with temporary wires	Desired rate for optimal hemodynamics	AV block	Output double the capture threshold
Synchronized cardioversion	0.5–1 J/kg	SVT, atrial flutter, atrial fibrillation	Sedation/analgesia needed
Defibrillation	3–5 J/kg	VT/VF	
External transcutaneous pacing	Increase output until capture; desired rate for optimal hemodynamics	Sinus bradycardia, AV block, junctional bradycardia	Temporary therapy in emergencies only
Esophageal pacing	Desired rate for optimal hemodynamics; overdrive for SVT	Sinus bradycardia, SVT	Not effective for AV block
Transvenous pacing	Desired rate for optimal hemodynamics; increase output until capture	AV block, sinus or junctional bradycardia	Temporary therapy; ineffective in single-ventricle patients

SVT, supraventricular tachycardia; AV, atrioventricular; JET, junctional ectopic tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation; PVC, premature ventricular contraction.

including the increase in endothelin levels, is the highest risk period for a PH crisis (159). In one series from the 1990s, severe PH was seen in 2% of postoperative cardiac patients, and such crises were fatal in almost 10% of such patients (160). This is certainly not the case today, and indeed the severe crises are unusual and accordingly are not recognized promptly. More often in the modern era, the single-ventricle patient, either after systemic-to-pulmonary shunt in the neonatal period, or bidirectional cavopulmonary anastomosis at 2 to 6 months of age, has a relatively subtle degree of elevation of PA pressure and resistance, which by objective criteria such as SVC pressure after surgery, is not impressive; however, the combination of single systemic ventricle that may have impaired systolic or diastolic function, AV valve regurgitation, and hypoplastic PAs, may elevate PAP just enough to cause a marginal patient to decompensate with hypoxemia and further elevations of caval pressures (161). In these patients, PAP can be normal in spite of increased PVR.

Another category of PH patients includes those with left-sided obstructive lesions, including mitral valve stenosis, cor triatriatum, pulmonary vein obstruction, and total anomalous pulmonary venous return (TAPVR) with obstruction. Left ventricular dysfunction such as in cardiomyopathy can also cause significant elevations in PA pressure and resistance. Besides the post-CPB-induced changes, excessive catecholamines, particularly induced by painful or noxious procedures such as tracheal suctioning, can precipitate severe PH crises. Airway and ventilatory problems such as hypoxemia, hypercarbia, and acidosis can also precipitate undesirable PAP elevations. Vigilance to anticipate and prevent PH crises is crucial in such patients.

Diagnosis

Short of a PH crisis (see below), elevated PAPs may cause right or single ventricular dysfunction, increased right-to-left shunting

through atrial or ventricular communications resulting in arterial desaturation, and inability to progress in weaning from mechanical ventilation. Some of these signs may be relatively subtle in the context of a ventilated patient with parenchymal lung disease. Bedside echocardiography is an important tool to assess right ventricular function and estimate PAP from the tricuspid regurgitation velocity, gradient across a VSD, or directionality of shunting at atrial or ventricular level. Position of the inter-ventricular septum is an important component of the examination, with midposition or right-to-left excursion during systole important accompaniments of significant PH. Patients suspected to have PH, and not progressing in their CICU course, should have hemodynamic catheterization to formally assess pulmonary hemodynamics and response to pulmonary vasodilator therapy.

The definition of PH crisis is an acute elevation in PAP to greater than half systemic that results in decreased pulmonary blood flow such that CO is compromised. This is heralded by poor peripheral perfusion, acidosis, and hypotension. Causes of acute PH crises are often inadequate analgesia and sedation before noxious stimulation, that is, tracheal suctioning or painful procedures. Other leading causes include airway and ventilation problems leading to hypoxemia and hypercarbia. If pulmonary blood flow is severely compromised, arterial desaturation will occur, and if an avenue for intracardiac right-to-left shunting exists, hypoxemia can be severe. Decreased blood flow through the lungs can compromise LV filling and coronary perfusion pressure and cause both left and right ventricular dysfunctions. Severe PH can cause acute RV failure. Acute difficulty with ventilation can occur as hypertensive distended pulmonary arterioles compromise small airway lumens. If such a PH crisis is not interrupted, a vicious cycle of hypoxemia and acidosis leads to ongoing severe PH and cardiac arrest. Early intervention is crucial to prevent such a disaster. Figure 20.5 illustrates the pathophysiology of a PH crisis. Echocardiography during an acute crisis will show a dilated poorly functioning RV with the ventricular septum bowing right to left, increased tricuspid

Figure 20.5. Pathophysiology of a pulmonary hypertension crisis. PH, pulmonary hypertension; mPAP, mean pulmonary artery pressure; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; CO, cardiac output.

regurgitation velocity, and decreased LV function. In the modern era, direct transthoracic measurement of PAPs or measurement with a Swan Ganz catheter is relatively infrequent, but if these modalities are available elevation to near or systemic suprasystemic pressures will be seen. If SVC pressure line is present in a bidirectional Glenn (BDG) circulation, elevation of this pressure to 20 to 25 mm Hg or higher will be seen.

Treatment

Urgency of treatment depends on the clinical situation but cornerstones of treatment of PH include ensuring an adequate airway to provide oxygenation and ventilation to treat hypoxemia and hypercarbia (162–164). Adequate sedation and analgesia are necessary to reduce endogenous catecholamine secretion. In certain high-risk preoperative patients, prophylactic iNO started during CPB weaning is effective at reducing severity and number of PH crises (165). Assessment of any treatable anatomic causes, that is, pulmonary vein obstruction, PA stenosis, is important. Assessing RV function and providing support for the RV in the form of milrinone to attempt both to lower PAP and improve RV systolic and diastolic function are important (124). iNO is frequently used in the acute setting (166). Sildenafil, administered orally or IV, is often effective at lowering PA resistance enough to improve the patient's condition (167).

Treatment of a PH crisis requires simultaneous institution of multiple modalities to prevent severe cardiovascular compromise. Controlling the airway, hyperventilating with 100% oxygen to achieve alkalosis are crucial, as are sedation and muscle relaxation to facilitate ventilation. Opioids, especially fentanyl, have been proven effective at preventing and treating severe PH. A dose of 5 to 25 $\mu\text{g}/\text{kg}$ is given along with adequate muscle relaxants (168). Volume boluses to increase pulmonary blood flow and LV filling are important. Epinephrine bolus, 1 to 5 $\mu\text{g}/\text{kg}$, is often effective at acutely increasing RV and LV function and increasing systemic blood pressure until other therapies are effective. iNO should be instituted emergently at 20 to 40 ppm; IV sildenafil can be instituted, inhaled nebulized prostacyclin is another alternative (169). In some severe cases of significant cardiopulmonary compromise, or cardiac arrest, ECMO can be used to rescue the patient.

After a PH crisis, weaning from the modalities instituted to lower PAP must be done gradually, and in a staged fashion, with careful assessment of PH at each step. While weaning iNO, administration of IV or oral sildenafil is effective in

preventing rebound PH (170). Although iNO is used very frequently in the CICU, it is a very expensive therapy with side effects such as NO_2 buildup, which is toxic to the lungs, methemoglobinemia, and rebound PH. If iNO is started, its use must be re-evaluated frequently with primary reason to continue being that the patient has responded to the therapy with improved oxygenation, improved CO, or in the case of direct PAP measurement, sustained lowering of PAP.

THE PULMONARY SYSTEM, VENTILATION, AND AIRWAY MANAGEMENT

Endotracheal intubation and mechanical ventilation are most often utilized in the CICU following cardiac surgery to ensure a patent airway and produce adequate oxygenation and ventilation while the patient recovers from the multisystem stresses of CPB. Although an inflammatory capillary leak syndrome is often seen after CPB, severe lung injury similar to adult respiratory distress syndrome (ARDS) is unusual, and most patients can be weaned from the ventilator in a relatively short time as bleeding subsides, cardiac function recovers, and generalized edema improves. Other indications for mechanical ventilation in the CICU are similar to the general PICU population, including cardiac failure with interstitial and alveolar pulmonary edema causing respiratory failure, primary pulmonary disorders such as pneumonia, upper airway obstruction, or central nervous system depression from sedatives or pathologic conditions necessitating control of the airway. Optimizing mechanical ventilation strategies will lead to faster improvement in pulmonary dysfunction, less time on the ventilator, and better overall outcomes (171).

Cardiorespiratory Interactions

Interactions between ventilation techniques and cardiac filling and output are most important in patients with a single functional ventricle (see Chapter 22). Infants with a single ventricle providing both systemic and pulmonary blood flow have complete intracardiac mixing, and manipulation of PVR using ventilator strategies may profoundly affect pulmonary-to-systemic blood flow ratio ($Q_p:Q_s$). This is particularly true with patent ductus arteriosus (PDA)-dependent systemic blood flow such as in HLHS. Hyperoxygenation and hyperventilation may lead to low CO and even cardiovascular collapse by excessively lowering PVR and greatly increasing $Q_p:Q_s$, leading to both ventricular volume overload and steal of blood flow from the systemic circulation (see Chapter 48). After a Stage I palliation, or other surgery replacing the PDA with a modified systemic-to-pulmonary artery shunt, variations in $Q_p:Q_s$ with ventilation are restrained by the fixed small shunt size; but basic physiologic considerations are the same. After the bidirectional cavopulmonary anastomosis, single-ventricle patients are still subject to adverse effects of hyperventilation; in this instance, low PaCO_2 will constrict cerebral arterioles and cerebral blood flow, leading to less pulmonary blood flow and thus less oxygenation (172,173). Finally, in single-ventricle patients after Fontan completion, the total cavopulmonary connection serves as the pulmonary circuit without benefit of a right ventricle contracting and adding kinetic energy to improve pulmonary blood flow. Blood flow depends largely on passive flow from systemic veins and the vena cavae into the thorax, greatly aided by the slightly negative intrathoracic pressure of spontaneous ventilation to provide a pressure drop to promote blood flow. Positive pressure mechanical ventilation presents a significant disadvantage in the Fontan circulation. Thus, minimizing positive pressure, allowing spontaneous breaths as early as possible, and extubating the trachea are important to minimize this disadvantage to pulmonary blood flow (174).

Figure 20.6. The effect of positive pressure ventilation on systemic ventricular transmural pressure. The decreased ventricular wall tension with positive intrapleural pressure will decrease the work of the systemic ventricle. (Reproduced from Stayer SA, Hammer GB. Chapter 18: Ventilatory management. In: Andropoulos DB, Stayer SA, Russell IA, Mossad EB, eds. *Anesthesia for Congenital Heart Disease*. 2nd ed. Oxford, UK: Wiley-Blackwell, 2010:338–354, with permission.)

One pathophysiology where positive pressure ventilation is often advantageous is in left ventricular failure. In this state, the negative pressure surrounding the aorta that accompanies spontaneous respiration increases the pressure gradient thus increasing the ventricular wall tension. Adding positive intrathoracic pressure can reduce this gradient and promote forward flow (Fig. 20.6) (175).

In recent years, emphasis has been placed on gentler mechanical ventilation to reduce the incidence of barotrauma and volutrauma (see below). Excessive tidal volumes and peak pressures may not only injure the lung, but can also elevate PVR as overdistended alveoli compress and occlude small pulmonary arterioles. Excessive ventilation also increases the inflammatory response in patients with PH, presumably from lung injury (176). Conversely, inadequate end-expiratory pressure may lead to collapse of lung units, and similar compression of pulmonary arterioles and elevation of PVR (175) (Fig. 20.7).

Positive pressure mechanical ventilation is frequently needed in the CICU, but the level of mean, peak, and end-expiratory pressure necessary to provide adequate oxygenation and ventilation must always be balanced against the potential negative effects of reducing venous return. Besides the single-ventricle patient, the most common of the dilemmas include the hypovolemic patient and the patient with pericardial effusion or tamponade, where even modest increases in intrathoracic pressure will impede venous return enough to significantly decrease cardiac filling. In general, patients receiving significant amounts of positive pressure ventilation will require higher cardiac filling pressures and intravascular volume status to maintain CO goals. Patients receiving high ventilator pressures that affect CO by conventional ventilation should be considered for alternate strategies such as high-frequency oscillatory ventilation (HFOV) or even ECMO.

Conventional Ventilation Strategies

Large tidal volume ventilation of 10 to 15 mL/kg, and low levels of positive end-expiratory pressure (PEEP 2 to 4 cm H₂O) were often used in the past with the thought that this strategy would lead to better recruitment of inhomogeneous alveolar units throughout the lungs. This strategy is now generally accepted to be a cause of significant lung injury, with both volutrauma and barotrauma occurring from shear stresses in compliant lung units and from high peak airway pressures. Contemporary strategies using tidal volumes of 6 to 8 mL/kg, higher PEEP of 5 to 7 cm H₂O, and limitation of peak pressures to no more than 30 cm H₂O are felt to provide lung recruitment while avoiding lung injury. Pressure limited, or pressure limited-volume controlled modes are often preferred for newly ventilated patients after surgery or intubation for medical illnesses. Inspiratory:expiratory ratios of 1:2 to 1:3 are preferred to allow adequate time for expansion of alveolar units with differing time constants for filling. Excessive inspired oxygen levels are toxic to the lungs causing oxidative damage through generation of oxygen free radicals and toxic oxygen species. FiO₂ should be 1.0 for intubation in most patients, but should be reduced as soon as tolerated to levels below 0.60, a level not generally associated with oxygen toxicity. These strategies have reduced mortality and morbidity, including less days on the ventilator in pediatric patients with acute lung injury (177,178). Obviously, many patients with CHD have right-to-left intracardiac shunting. Thus, they have a ceiling level of PaO₂ or SpO₂ achievable with FiO₂ 1.0, but these patients

Figure 20.7. Relationship of lung volume to pulmonary vascular resistance. Both low and high lung volumes compress pulmonary arterioles, leading to increased PVR. FRC, functional residual capacity. (Reproduced Stayer SA, Hammer GB. Chapter 18: Ventilatory management. In: Andropoulos DB, Stayer SA, Russell IA, Mossad EB, eds. *Anesthesia for Congenital Heart Disease*. 2nd ed. Oxford, UK: Wiley-Blackwell, 2010:338–354, with permission.)

are still subject to pulmonary injury and fibrosis from excessive oxygen. Patients should be allowed to initiate spontaneous breaths, and to do as much of the work of breathing as they can, assisted by pressure- or volume-supported breaths: 5 to 10 cm H₂O added pressure or 3 to 5 mL/kg added volume. This is necessary to exercise the diaphragm and intercostal muscles, and will also allow lower mean airway pressures and promote venous return to improve CO. Heavy sedation or muscle relaxation that prevents spontaneous breaths can lead to atrophy of these muscles and prolong time on the ventilator. Because the endotracheal tube (ETT) bypasses the natural defenses of the upper airway, and coughing and ciliary function are impaired, ventilator-associated pneumonia (VAP) is a constant threat in the intubated patient. The simple strategy of elevating the head of the bed of a ventilated patient 30 degrees, along with implementation of a relatively simple “bundle” of other strategies will prevent the majority of VAP (179). A defined program of pulmonary toilet, including suctioning, inhaled bronchodilators, chest physiotherapy, and bronchoscopy to open persistent areas of atelectasis, is important to maintain gas exchange and allow progress toward extubation. Daily chest radiographs are indicated in most intubated patients to assess position of endotracheal tube, status of lung parenchyma including atelectasis, pulmonary edema, pleural effusion, pneumothorax, cardiomegaly, and pericardial effusion. These problems should be aggressively treated in order to shorten the period of mechanical ventilation. Multiple studies document that longer duration of mechanical ventilation is associated with worse long-term morbidity, and mortality (180,181).

Monitoring of ventilation includes continuous pulse oximetry and also should include continuous monitoring of ET_{CO}₂. The latter is becoming more frequent in PCI-CUs; the advantages include a continuous assessment of gas exchange with sudden changes and early warning sign of airway obstruction in the case of hypercarbia or low CO and pulmonary blood flow (182). Ventilator disconnection is immediately recognized. Monitoring of ventilatory volumes, pressures, and resistances using sensors inside modern ventilators has limited utility in small pediatric patients. This is because the ventilator tubing itself has a dead space where no gas exchange occurs, and a portion of the tidal volume is absorbed in the mechanical expansion of the tubing with positive pressure ventilation, which is a significant proportion in small infants. Ventilator systems designed for adults cannot adequately compensate or measure pulmonary mechanics in small infants. A much more accurate measurement of pulmonary mechanics is acquired with infant pulmonary function monitors attached directly to the end of the endotracheal tube (183). These devices are integrated into many modern neonatal ventilators, or can be used as stand-alone monitors for intermittent assessment.

Weaning from Mechanical Ventilation

Weaning from mechanical ventilation may be as simple as a brief trial of spontaneous ventilation with continuous positive airway pressure (CPAP) in a postoperative patient with no parenchymal lung disease immediately after surgery, to a prolonged period of gradual weaning ventilator settings, and the patient taking over more and more of the work of breathing, over many days or sometimes weeks (184). To be ready to wean from the ventilator, the patient should have a mental status evaluation done, which assures that after reducing sedation patent airway and protective airway reflexes are maintained. Ventilator settings should be low enough to begin weaning, usually FiO₂ of 0.40 or less acceptable lung compliance and resistance with peak pressures below 25 to 20 cm H₂O and PEEP

5 mm Hg or less. A very effective strategy is to allow the patient periods of spontaneous respiration with volume-supported breaths, of 3 to 6 mL/kg, starting with short periods of 30 to 60 minutes at a time, and gradually lengthening these periods, judged by the patient's work of breathing, and blood gas values at the end of these volume support trials. When the patient is able to sustain adequate arterial blood gases (ABGs) with acceptably low work of breathing, extubation is considered. Quantitative measures for readiness for extubation in infants and children, that is, negative inspiratory force, forced vital capacity, minute ventilation, have limited utility. Clinical examination, chest radiograph, and blood gases are better used to determine readiness. A useful measure is the rapid shallow breathing index (RSBI), which equals respiratory rate/tidal volume (185). Lower RSBI is correlated with readiness for extubation; that is, better lung function indicated by lower respiratory rates and larger tidal volumes. Particularly in small infants, whose small airways are easily traumatized and where even a limited amount of mucosal edema may narrow the subglottic airway considerably, dexamethasone 0.25 mg/kg IV Q 6h for 12 to 24 hours, is effective in preventing upper airway obstruction and nebulized racemic epinephrine treatments are useful for signs of significant upper airway edema (186). Patients who are considered for tracheostomy have prolonged mechanical ventilation from cardiac, pulmonary, and/or airway causes; progress toward extubation is not being made; and need for excessive doses of sedation is interfering with other aspects of general care (187). There are no set guidelines for tracheostomy in pediatric cardiac patients. This is a complex undertaking that complicates future cardiac surgeries because of the proximity of the airway to the sternotomy incision increasing the risk of infection. Patients with CHD, particularly single-ventricle infants on chronic ventilation via tracheostomy, have a high mortality rate (188). Multidisciplinary decision making is necessary, and tracheostomy should be considered a last resort in cardiac patients.

Endotracheal Intubation and Airway Management

The decision to intubate the trachea and institute mechanical ventilation is made when respiratory distress, diagnosed by observing for significant tachypnea, retractions, cyanosis with SpO₂ often 10% or more lower than baseline and significant hypercarbia, is causing low CO, or heralding risk for respiratory arrest. Chest radiographs often show significant pulmonary edema, lobar, or whole-lung infiltration or collapse, or significant cardiomegaly causing airway compression. Short of intubation, noninvasive ventilation methods as outlined below are sometimes useful while other medical therapy is given time to be effective. Arterial blood gases are the gold standard for assessing gas exchange, and often an arterial catheter is present in the CICU patient who is being considered for intubation. If not, capillary blood gas, chest radiography, pulse oximetry, and clinical assessment can give the necessary information. Early intervention before severe cardiopulmonary compromise is the goal. However, intubating the trachea and instituting positive pressure ventilation has potential for severe hemodynamic compromise in the patient with marginal cardiopulmonary status. Emergency tracheal intubation in cardiac patients, as opposed to proactive intubation before the patient is *in extremis*, is associated with higher complication rates, including mortality and need for mechanical support. (189).

Basic equipment and preparations for intubation include laryngoscopes and endotracheal tubes in appropriate sizes, oral airways, working suction immediately at hand, and high-flow oxygen source and manual ventilation bag that is easily operated, either of self-inflating type, or an anesthesia-type

configuration such as a modified Jackson-Rees bag. Methods to detect exhaled CO₂, either colorimetric or continuous monitors, are mandatory to ensure that the tube is in the trachea (190).

In general, FiO₂ of 1.0 is always recommended for pre-oxygenation and initial management immediately after ETT placement. Evaluation of the airway for possible difficult mask ventilation and intubation is mandatory before administering drugs that will render the patient apneic; the most common reason for difficulty in cardiac patients is micrognathia as seen in some patients with craniofacial syndromes that accompany their cardiac disease such as velocardiofacial syndrome or the Pierre-Robin sequence. If difficulty is anticipated, requesting assistance from an anesthesiologist or otolaryngologist is very important to avoid a disastrous “cannot ventilate, cannot intubate” situation. Also, a full stomach mandates suction of gastric contents before intubation where possible and cricoid pressure during mask ventilation before intubation. The infant’s head position is neutral. A small towel is placed under the occiput in an older child to achieve the “sniffing position” during laryngoscopy to align the axes of the pharynx, larynx, and trachea. The patient is preoxygenated with a tight-fitting face mask for 3 to 5 minutes if possible, induction drugs are given, and positive pressure ventilation is instituted early and gently. Jaw thrust or oral airway are used if there is inadequate chest rise with bag and mask ventilation. Cricoid pressure is applied by an assistant in the case of a child who has a full stomach. With loss of consciousness and adequate muscle relaxation, the laryngoscope is inserted into the right side of the mouth, the tongue swept to the left out of the midline, and the blade advanced until the epiglottis is visualized. The blade is advanced further into the vallecula with a curved blade, or under the epiglottis with a straight blade, the handle lifted with a gentle upward motion at a 45 degree angle to the surface of the bed, and position adjusted until the arytenoid cartilages and vocal cords are in view. The “BURP” maneuver (Backward, Upward, Rightward Pressure) on the cricoid cartilage by an assistant often is very effective to improve visualization. The ETT with a stylet bent at a 45 degree angle (“hockey stick” configuration) is inserted by direct visualization, taking care to insert the tube to the correct depth using markings on the tube and guidelines for the tube size. In modern practice, a cuffed ETT is recommended for virtually all CICU patients with the

exception of some small neonates where an uncuffed 3.0- or 3.5-mm ETT is used. A common guide to ETT size selection is:

$$16 + \text{Patient age (years)} / 4$$

For example, 5.0-mm ETT $((16 + 4) / 4 = 5)$ will be used in a 4-year-old patient. Since this formula was developed for uncuffed ETT, many practitioners will use the cuffed ETT 0.5 mm smaller, that is, a 4.5-mm cuffed ETT for a 4-year old.

Ventilation ensues gently; excessive positive pressure in combination with the cardiovascular depression often seen with induction drugs can result in cardiovascular collapse. Breath sounds are auscultated, the stomach is also auscultated to help rule out esophageal intubation. Detection of CO₂ that is persistent for 6 or more breaths is a critical confirmatory step. If there is no ETCO₂, causes include esophageal intubation, poor pulmonary blood flow, cardiac arrest, or severe bronchospasm preventing gas exchange. If this occurs, the first reaction is often to remove the ETT and reinsert; however, strong consideration should be given to having the most experienced airway manager perform a direct laryngoscopy, and often the ETT will indeed be correctly positioned. This avoids the unnecessary situation of the inappropriate removal if the ETT in an arrested patient. Blood pressure, heart rate, and SpO₂ must be followed carefully immediately after tracheal intubation. Patients will sometimes require intravascular volume bolus or pressors, such as a small dose of epinephrine, to restore desirable hemodynamics. In the case of a very tenuous patient, a full cardiac arrest should always be anticipated.

Depth of insertion of the ETT is crucial, especially in small infants where total length of the trachea may be only 4 to 5 cm. Using the depth markings on the tube, the ETT is advanced until the desired mark is at the level of the vocal cords. The chest is auscultated for equal breath sounds. A chest radiograph is obtained as soon as possible after securing the tube. Other methods of estimating proper orotracheal depth of insertion include deliberately placing the tube in the right mainstem bronchus, and then auscultating the left chest during rapid hand ventilation while the tube is being withdrawn. When breath sounds appear, the ETT is at the carina; the tube is then withdrawn another 1 to 1.5 cm for final positioning.

TABLE 20.8 Endotracheal Tube and Laryngoscope Blade Sizes

Age	Weight (kg)	ETT Size (mm)	Laryngoscope Blade
Premature neonate	<2.5	3.0 uncuffed	Miller 0
Full-term neonate	2.5–4	3.5 uncuffed or cuffed	Miller 1
1–6 mo	4–6	3.5 cuffed	Miller 1
6–12 mo	6–8	3.5–4.0 cuffed	Miller 1, Wis-Hipple 1.5
1–2 y	8–10	4.0–4.5 cuffed	Wis-Hipple 1.5
2–3 y	10–12	4.5 cuffed	Wis-Hipple 1.5, MacIntosh 2
4–5 y	12–18	4.5–5.0 cuffed	MacIntosh 2, Miller 2
5–7 y	18–24	5.0–5.5 cuffed	MacIntosh 2, Miller 2
8–10 y	24–35	5.5–6.0 cuffed	MacIntosh 3, Miller 2
11–13 y	35–40	6.0–6.5 cuffed	MacIntosh 3, Miller 2
14–16 y	40–50	6.5 cuffed	MacIntosh 3, Miller 2
16 y and above	50 and over	7.0–7.5 cuffed	MacIntosh 3, Miller 2

TABLE 20.9

Medications for Sedation and Muscle Relaxation for Endotracheal Intubation

Medication	Dose	Comments
Fentanyl	1–5 µg/kg	Titrate to effect; chest wall rigidity
Midazolam	0.025–0.1 mg/kg	
Ketamine	1–2 mg/kg	
Etomidate	0.2–0.4 mg/kg	Best for hemodynamic stability; temporary adrenal suppression
Propofol	1–2.5 mg/kg	Veno- and vasodilator
Vecuronium	0.1–0.2 mg/kg	No hemodynamic effects; muscle relaxation in 2–3 min
Rocuronium	0.6–1.2 mg/kg	Minimal hemodynamic effect; muscle relaxation 1.5–2 min

Also, with an orotracheal tube, an estimate of proper distance is the ETT size multiplied by 3, that is, depth of 12 cm for a 4.0-mm ETT. Tables 20.8 and 20.9 describe ETT, laryngoscope blades, and drugs recommended for endotracheal intubation.

Alternate Ventilation Strategies—Noninvasive Ventilation

With the recognition that mechanical ventilation is a source of barotrauma, volutrauma and infection, recent years have witnessed resurgence in popularity of noninvasive ventilation techniques, either to prevent intubation, or as an immediate postextubation therapy to prevent reintubation. In neonates and small infants, nasal CPAP is often very effective and surprisingly well tolerated, and routine use of this modality after extubation in small infants is used in many PCICUs. CPAP of 5 to 10 cm H₂O for periods of 24 to 72 hours is often utilized (191). High-flow nasal cannula oxygen with humidified gas routed through a heated humidified circuit at flows of 5 to 10 L/min is also an effective therapy for patients of all ages. In older patients unable to tolerate nasal CPAP or where it is not effective, CPAP with a tight-fitting nasal mask or BiLevel Positive airway pressure, where assisted ventilation parameters can be provided, is often very helpful at avoiding intubation (192).

Early Tracheal Extubation

Besides the desirable hemodynamic advantages of negative pressure ventilation in the Fontan circulation, many centers have organized “fast-tracking” programs for early tracheal extubation after simple or even moderately complex cardiac surgery. Cited advantages include less need for sedation; more comfort for the patient, faster progress through the ICU, and avoidance of barotrauma and lower risk of nosocomial pneumonia. Extubation can be accomplished in the OR, or early in the ICU course in the first 1 to 4 hours. Institutional practices vary widely, from no early extubation in any patients, to aggressively extubating all possible patients, even including small infants who underwent moderately complex surgery

(193). Criteria for early extubation include hemodynamic stability on minimal or no inotropes, normal sinus rhythm, minimal bleeding, minimal pulmonary disease, low doses of fixed anesthetic agents, reversal of muscle relaxants allowing appropriate neuromuscular status, and ability of the ICU nursing staff, anesthesiologists, or intensivists to monitor and support the patient airway after extubation, including timely reintubation. A careful and cautious approach is recommended to avoid the situation of having to reintubate a patient who is unstable for 6 to 12 hours after surgery from bleeding, inflammation, and hemodynamic compromise. Multidisciplinary collaboration is important in any early extubation program (194).

High-Frequency Oscillatory Ventilation

When conventional ventilation fails to produce adequate gas exchange despite high ventilator pressures and FiO₂, the ventilator therapy is interfering with CO and/or there is risk for barotrauma, HFOV should be considered. HFOV can be used as a rescue therapy for hypoxemia refractory to conventional mechanical ventilation. It is also used as a means of reducing shear forces the lung is exposed to with conventional ventilation. HFOV uses a rapidly oscillating piston mechanism to actively push gas into the lungs, and remove it by negative pressure with tidal volumes much smaller than conventional ventilation. Oscillation frequency is set at 6 to 14 Hz. The mean airway pressure is generally higher than with conventional ventilation, allowing recruitment of lung units with different time constants. However, the pressure variation, including the peak pressure, is significantly lower, and this often leads to better gas exchange with lower risk of barotrauma. HFOV is often utilized in pediatric patients with ARDS and very noncompliant lungs, and may improve gas exchange. However, conclusive proof is lacking that this strategy improves outcomes, including days ventilated and survival (195,196).

GENERAL POSTOPERATIVE CARE

The majority of admissions to most CICUs are postoperative patients, and a coordinated, multidisciplinary approach to their care is important to facilitate the best outcomes (197,198). Ideally, the care of these patients begins preoperatively, where many CICUs will admit neonatal patients with prenatal diagnoses directly from the delivery room or after transfer when a diagnosis of CHD requiring surgery is made. A multidisciplinary surgery conference greatly facilitates communication among the many disciplines caring for the patient. This should be at least a weekly conference where upcoming patients have their pertinent history, physical examination, radiographic, echocardiographic, catheterization, MRI, and/or CT scan findings presented. This is usually done by a primary cardiologist or fellow. The conference is attended by cardiologists, congenital heart surgeons, intensivists, neonatologists, anesthesiologists, perfusionists, nursing staff from OR and ICU, and trainees from all the services. It serves as both a working conference to plan surgery and as a teaching conference. Findings are discussed, and a surgical plan is decided. The CICU staff has active input into the preoperative decision-making process, is made aware of the planned schedule each week, and can prepare for each patient. The key to successful preoperative planning conferences is concise, organized presentations of each patient with a focused discussion resulting in concrete plans. The postoperative care plan begins with the preoperative conference.

Handoff

The handoff of care from the OR team to the CICU team is an important time where crucial information about the surgery is

CARDIOVASCULAR ANESTHESIA POSTOPERATIVE - ICU Procedure Note

Date: _____ **Time:** _____ **Diagnosis:** HLHS (mitral/aortic atresia)
Procedure: Norwood Stage I palliation; 3.5 mm right modified BT shunt
General Anesthesia: Fentanyl 95 mcg/kg, midazolam 0.75 mg/kg, isoflurane
Muscle Relaxant: vecuronium **Reversed:** No
Regional Anesthesia: NA
Total CPB Time: 161 minutes **Aortic Cross Clamp Time:** 90 minutes
DHCA Time: 10 minutes **Lowest Temp:** 17.6° C
ACP Time: 52 minutes
Phentolamine: 0.3 mg/kg on CPB **Antibiotic:** Cefazolin: Time of last dose: 1310
Post Op Rhythm: NSR Paced: NA—atrial pacing wires x2 Other: NA
Vasoactive Infusions: Epinephrine 0.03 mcg/kg/min, milrinone 0.375 mcg/kg/min (no loading dose); CaCl₂ 10 mg/kg/hr.
Heparin: Yes **Protamine:** Yes **ACT to Baseline:** Yes—123 seconds
Post-CPB Blood Products: PRBC 15 ml, platelets 45 ml; cryoprecipitate 1 unit
Other Fluids: 5% albumin 25 ml; D5W carrier 45 ml
Urine Output: 27 ml **EBL:** NM **Final Hct:** 44% **Final ABG:** 7.37/43/4
1/BE 0
Other Drugs: ε-aminocaproic acid; methylprednisolone
ETT: 3.5 nasal cuffed, taped 11.5 cm; **Drains:** Mediastinal x 2; peritoneal dialysis
leak 25 cm H₂O catheter, foley catheter
Vascular Access: 22 g L radial arterial line; 3.5 Fr UAC; L femoral venous 4 fr double lumen
CVP; 22g PIV R saphenous vein.
Postop TEE: Mildly depressed systolic RV function; minimal tricuspid regurgitation, no
neo-aortic insufficiency; open unrestrictive atrial septum; good flow seen
both pulmonary arteries.
Comments: Generally stable intraoperative course. Weaned from CPB easily, moderate bleeding
responded to platelet and cryoprecipitate infusion. Sternum closed without major
hemodynamic/respiratory change. Transported to CICU, full report given to MD and RN teams, care
transferred.

Figure 20.8. Template for handoff of care from OR to cardiovascular intensive care unit.

communicated in a clear and concise manner (199). Failure to communicate handoff information accurately in a manner that is fully understood by the receiving team is a frequent cause of medical errors that can adversely affect patient outcome (200,201). After transfer of the patient to the CICU transfer of monitors and establishment of ventilation, the handoff report begins. All involved need to be present: CICU attending, fellow, resident, nurse, respiratory therapist, and surgeons should be present. Usually, the anesthesiologist will give a standardized report that summarizes the OR course, including pre-bypass period, surgery done, CPB data including length of CPB, aortic crossclamping, deep hypothermic circulatory arrest (DHCA), and lowest intraoperative temperature. Inotropic support and other vasoactive therapy are detailed, along with results of the postoperative transesophageal echocardiography, including the presence of any residual defects (202). Anesthetic and other drug doses (antifibrinolytics, corticosteroids) are summarized, along with blood gas results, cardiac rhythm and pacing issues, bleeding problems, and blood product administration. Any problems are noted, along with general goals for early postoperative care, that is, early extubation. The timing of the last doses of sedatives and analgesics and antibiotics is reported. Whether the patient's neuromuscular blockade was reversed in the OR should be noted. A member of the surgical team should also be present who details the surgical procedure, and notes any residual lesions, that is, an atrial septal defect (ASD) left intentionally to serve as a pop off after right ventricular reconstructive surgery. The receiving team then has the opportunity to ask questions and formally assumes care of the patient. A

controlled, quiet environment, where all are paying attention to the information being transferred, is very important. A template for the CICU postoperative handoff is displayed in Figure 20.8. This becomes the medical record for the anesthesiologist's handoff report and can easily be adapted for EMR systems.

Effects of Cardiopulmonary Bypass

CPB has made modern congenital heart surgery possible, and the limits of patient size and complexity of surgery are continually expanded to make ever more difficult surgeries feasible. However, a myriad of CPB techniques are utilized, all of them institution or even surgeon specific, the CICU team must be aware of and be prepared to treat any number of sequelae of CPB (203–207). The basic CPB circuit arrangement is depicted in Figure 20.9 (208). The aorta is cannulated for arterial perfusion, and, in most CHD operations, bicaval cannulation of the SVC and IVC is used (Fig. 20.10). Alternately, the right atrium alone can be used for single cannula venous drainage. CPB is instituted after full heparinization, with activated clotting time (ACT) goals of normally 480 seconds to produce profound anticoagulation. CPB suction is used to return shed blood from the pericardial well to the venous reservoir of the CPB machine. Flow is provided by roller pumps, blood is oxygenated, CO₂ is removed, and extracorporeal heating and cooling are provided by a water bath and countercurrent mechanism within an integrated oxygenator/heat exchanger. Monitoring consists of arterial and venous pressures, in-line arterial and

Figure 20.9. CPB basic configuration. (Modified from Hessel EA, Hill AB. Circuitry and cannulation techniques. In: Gravlee GP, Davis RF, Kursz M, Utley JR, eds. *Cardiopulmonary Bypass: Principles and Practice*. Philadelphia, PA: Lippincott, Williams & Wilkins;69–97.)

venous blood gas and saturation sensors and bubble detectors. Modern oxygenators are hollow-fiber membrane designs that allow rapid transfer of oxygen and CO₂ across a very large surface area blood–gas interface with minimal pressure drop across the oxygenator.

Figure 20.10. Bicaaval cannulation for CPB in a neonate. This allows the surgeon access to intracardiac structures while allowing perfusion to continue, limiting the period of DHCA needed for complex intracardiac repairs.

Choice of CPB flows varies by institution but, in general, for infants is 150 mL/kg/min for full flows, and in older children body in whom surface area is used, full flow is 2.8 L/min/m² for older children, decreasing to 2.4 L/min/m² for larger children and teenagers. Cooling is routinely used for most operations to decrease myocardial, brain, and other organ oxygen consumptions, and preserving function during periods of low CPB flow. The degree of hypothermia is termed mild (30°C to 34°C), moderate (22°C to 30°C), or deep (17°C to 22°C). CPB flow is often decreased during hypothermia in many centers because this decreases blood return into the surgical field from bronchial, thebesian, and intracardiac sources, allowing the surgeon better visibility to perform the surgery. Some surgeons do not reduce CPB flow, reasoning that better blood flow to all organs and tissue beds improve recovery from CPB (209). Some surgery is accomplished with the heart beating; these are extracardiac operations such as bidirectional cavopulmonary anastomoses or simple pulmonary valve replacements. Intracardiac surgery necessitates a period of aortic crossclamping and delivery of high potassium cardioplegia to render the heart asystolic, allowing a near bloodless field. If a period of low flow or DHCA is planned, deep hypothermia is used. DHCA is a period where the CPB flow is stopped completely, the heart and patient are drained completely of blood, and a bloodless field is created to facilitate intracardiac surgery especially in small infants. Because prolonged periods of DHCA are associated with cerebral injury (see below), a recent variation is to use antegrade cerebral perfusion (ACP, also called selective cerebral

Figure 20.11. Antegrade cerebral perfusion. A graft is sewn to the right innominate artery, the brachiocephalic vessels and descending aorta are snared, and the brain is perfused during aortic arch reconstruction, in lieu of DHCA. (Modified from Pigula FA, Nemoto EM, Griffith BP, et al. Regional low-flow perfusion provides cerebral circulatory support during neonatal aortic arch reconstruction. *J Thorac Cardiovasc Surg* 2000;119:331–339.)

perfusion or RCP), where only the brain is perfused during deep hypothermia such as with aortic arch reconstruction during the Norwood Stage I palliation (210) (Fig. 20.11). Blood gas temperature management during CPB can be either α stat, not correcting for temperature, which causes significant alkalosis at deep hypothermia; or pH stat, in which blood gas values are corrected for temperature, resulting in “normal” pH and PCO_2 at deep hypothermia. Most centers now use hemofiltration, either during CPB or modified ultrafiltration immediately after CPB to remove excess intravascular and interstitial fluid and filter small molecules, including many mediators of inflammation.

CPB induces a number of sequelae that can affect postoperative care. Contact of the patient’s blood with components of the CPB circuit initiates a significant inflammatory response and activation of intrinsic and extrinsic coagulation pathways. Despite this well-known phenomenon, recent studies have not documented that the rate of adverse clinical outcomes is proportional to the magnitude of the inflammatory response (211). Many programs use corticosteroid treatment, usually with methylprednisolone, 10 to 30 mg/kg, given either 4 to 12 hours preoperatively or in the CPB prime to attempt to mitigate this inflammatory response. Despite widespread use and a demonstrated reduction in some of the inflammatory mediators (IL-6, -8, -10), published studies have not demonstrated a difference in outcomes with such treatment (212).

Red blood cells undergo hemolysis from trauma induced by pump suction, oxygenator, and passing through filters in the circuit. Periods of low-flow CPB or DHCA may result in ischemia to end organs such as kidneys, liver, intestines, and brain. The inflammatory response may induce capillary leak, resulting in edema in most tissues and organ systems, including pulmonary interstitial and alveolar edema. Long periods of

aortic crossclamping result in myocardial ischemia reperfusion injury, and myocardial dysfunction manifests in the immediate post-CPB period. Extensive intracardiac surgery, which includes resection of myocardium or long periods of retraction of intracardiac structures, can result in mechanical trauma including tricuspid regurgitation or arrhythmias such as JET or complete AV block. The profound anticoagulation needed for CPB, dilution of clotting factors, hemoglobin, and platelets as well as platelet dysfunction induced by activation from components of the CPB circuit increase the risk of bleeding, particularly in small infants. Extensive high-pressure suture lines, especially with aortic surgery, further increase this risk. Generally speaking, the risk of all of these sequelae increases with longer CPB times, aortic crossclamp times, and DHCA times. It is important to be aware of these issues from the report of the OR team, and to be vigilant for sequelae from long CPB times and complicated surgery. There is a well-documented decrease in CO in infant patients 6 to 12 hours after CPB, thought to be induced by the inflammatory response, which peaks at that time and interferes with intrinsic myocardial function and extrinsic catecholamine effect (213). This period often occurs in the late evening and early morning hours; thus, the overnight team must be vigilant for the possible need for increased support at these times.

Bleeding

As noted above, bleeding after CPB is a constant threat for the newly admitted CICU patient. Antifibrinolytic agents such as ϵ -aminocaproic acid and tranexamic acid are commonly used for complex infant cases or repeat sternotomy and are effective at reducing blood loss and blood transfusion. Heparin effect is reversed with protamine in the OR and is rarely the cause of ongoing bleeding in the CICU. Upon admission, a complete blood count with platelet count, prothrombin time partial thromboplastin time, and fibrinogen concentration should be measured. Some programs will also use thromboelastography as a functional test of coagulation (214).

In infants under 10 kg, the primary defect causing bleeding is poorly functioning platelets and a low platelet count. For these patients, platelet transfusion is the first-line therapy. The second most important defect is low fibrinogen. Thus, cryoprecipitate is often the next line therapy (215). Clotting factors themselves may be affected, but the CPB prime often contains fresh frozen plasma; thus, this is considered third-line therapy. Red blood cells in the form of banked blood or washed cell saver blood from the OR should be immediately available and given as needed to maintain hematocrit in the target range. Whole blood is rarely available. A recent study actually demonstrated worse bleeding when whole blood was used for CPB priming versus using reconstituted fresh whole blood with packed RBC and FFP from the same donor (216). Ongoing bleeding in the face of normal or near-normal coagulation studies usually heralds a surgical source of bleeding, and the surgeon should be consulted early to decide if the patient needs to return to the OR for mediastinal exploration. Blood pressure control is often important early in the postoperative course to limit bleeding from arterial sites and prevent major bleeding from dehiscence of arterial suture lines. Generally, total chest drain output of 10 mL/kg/h for 2 or more hours is considered excessive bleeding and if coagulation studies have been normalized, there should be strong consideration for surgical re-exploration. Early extubation is not advisable in the bleeding patient and the nursing staff must continually strip the chest tubes to ensure adequate drainage. If the chest tubes suddenly cease to drain and the patient has signs of tamponade including low CO and blood pressure, pulsus paradoxus, widened mediastinum on chest radiograph, elevation and equalization of atrial filling pressures, and fluid or thrombus around the heart demonstrated by bedside echocardiography, emergent

mediastinal exploration is indicated to remove thrombus and blood and stop surgical bleeding sources. The intensivist must be vigilant early in the ICU course, particularly in small infants with very limited mediastinal volumes in whom even a small amount of accumulated clot or blood can cause tamponade.

Delayed Sternal Closure

Many infants or other patients who have had extensive surgery causing bleeding, arrhythmias, or hemodynamic instability are candidates to have the sternum left open immediately postoperatively in order to leave maximum space for any bleeding, or mediastinal edema that could adversely affect CO, especially with positive pressure ventilation. Usually, a plastic strut made from a chest tube is sewn to the sternum to hold it open, and covered with a synthetic patch and an iodine impregnated plastic adhesive dressing. This allows rapid access to the mediastinum, and a full mediastinum is easily detected with bulging of the patch. Bedside exploration is often possible. If the patient is very unstable, easy access for ECMO cannulation is possible. When the patient is more stable at 24 to 72 hours postoperatively with no bleeding, acceptable hemodynamic and respiratory status, the sternum is closed at the bedside in the CICU, normally with the OR and anesthesia teams providing support for the surgeon. Sternal closure may induce adverse hemodynamic changes and the intensivist must be vigilant in the early hours after the procedure (217).

PERIOPERATIVE CONSIDERATIONS FOR SPECIFIC LESIONS AND PROCEDURES

This section summarizes the most important perioperative considerations for major lesions encountered in patients admitted to the CICU. The reader is referred to the corresponding chapters for detailed discussion of anatomy, pathophysiology, and diagnostic and treatment considerations for each lesion.

Hypoplastic Left Heart Syndrome

Many HLHS patients are prenatally diagnosed and delivered in a referral center. If there is no perinatal cardiorespiratory depression, the majority of these patients do not need tracheal intubation. PGE₁ is instituted immediately after birth, umbilical vessel catheters are placed, and the patient is transferred to the NICU or CICU while breathing room air. Most of these patients can be managed on room air with spontaneous ventilation before surgery, with careful monitoring of cardiorespiratory status. Arterial blood gas values, along with serum lactate concentration, should be measured at regular intervals. The former practice of tracheal intubation and sedation and ventilation with low FiO₂, including subambient oxygen levels, has been demonstrated to lead to significantly decreased cerebral and somatic oxygen delivery, should be avoided (218). Decreasing PVR in the first several days is heralded by increasing SpO₂, progressive tachypnea, and interstitial edema. Diuretic therapy with furosemide is instituted as needed. Vigilance for signs of decreased systemic perfusion is important, including mesenteric perfusion, which may lead to necrotizing enterocolitis. Feeding is limited to parenteral nutrition and possibly intestinal trophic feeds via nasogastric tube. Tracheal intubation is performed for significant respiratory distress or hemodynamic compromise. The Norwood Stage I palliation or hybrid procedure should be performed in the first week of life if possible. Infants referred with a postnatal diagnosis, especially if late, that is, after 3 to 5 days, may require

resuscitation from shock as the ductus narrows or closes (219). These infants will require mechanical ventilation and inotropic support. End-organ injury, that is, renal, hepatic, gastrointestinal, and CNS, should be investigated and stabilized before proceeding for surgery. Patients with very restrictive or intact atrial septum diagnosed *in utero* require emergent evaluation and intervention immediately after birth, with BAS, atrial septectomy, or the complete Stage I repair (220,221).

The Stage I palliation involves reconstruction of the aorta from native pulmonary valve, native aortic valve and aorta, and homograft material. This is done with DHCA in many centers, or ACP in others. Pulmonary blood flow is provided by a systemic-to-pulmonary artery shunt, normally 3 to 4 mm polytetrafluoroethylene (PTFE) graft, from innominate-subclavian artery to right pulmonary artery, or by a right ventricle to pulmonary artery conduit, usually 5- to 6-mm PTFE graft (Sano modification). Heparin infusion at low doses is begun in most centers after the BT shunt, 6 to 12 hours postoperatively, and continued until the patient is able to take aspirin. Early postoperative hemodynamic stability may be better with the Sano modification, because of higher diastolic blood pressure and thus better coronary perfusion. However, systemic

Figure 20.12. Variations in shunt type for hypoplastic left heart syndrome. Classic right modified Blalock-Thomas-Taussig shunt (top), and Sano modification (bottom) that provides pulmonary blood flow via right ventricle to pulmonary artery conduit. (Redrawn from Ohye RG, Sleeper LA, Mahony L, et al. Comparison of shunt types in the Norwood procedure for single-ventricle lesions. *N Engl J Med* 2010;362:1980–1992.)

oxygen saturations are generally lower with the Sano, but cerebral oxygen saturation and diastolic cerebral flow velocities are not different (222). A recent multicenter controlled trial of BT shunt versus RV-PA conduit demonstrated survival advantage with the RV-PA conduit at 12 months of age (223) (Fig. 20.12). However, after age 12 months, the differences in rate of death or transplantation were no longer significant. Early postoperative management involves balancing $Q_p:Q_s$ to be as close to 1:1 as possible; desaturated patients with high PVR may require higher FiO_2 and iNO, or possibly enlargement of the BT shunt (225). Most patients have the problem of PVR that is relatively low, and decreasing FiO_2 and minute ventilation to increase $PaCO_2$ will elevate PVR and help achieve balance, and in severe cases the shunt may require downsizing. Inotropic support with dopamine, epinephrine, or milrinone is usually required, and the sternum is often left open for 24 to 72 hours. Figure 20.13 illustrates priorities in pathophysiologic approach to single-ventricle neonates (224). Bleeding may be significant, and treatment with platelets, cryoprecipitate, red blood cells, and fresh frozen plasma is often necessary. ECMO support is at times necessary, either for low cardiac output or cardiac arrest. HLHS is not a contraindication to mechanical support in most centers. (225)

The hybrid repair of HLHS is performed in a specially designed catheterization laboratory or OR where fluoroscopy is available. This is done without CPB. After sternotomy, the pulmonary arteries are banded by the surgeon and the PDA is stented by the interventional cardiologist, along with a stent in the atrial septum, placed either at the initial operation or later by standard catheterization techniques (226). The advantages of this approach are the avoidance of CPB, DHCA, or ACP in the neonate. However, hybrid HLHS patients are often

hemodynamically unstable in the first 24 to 48 hours with low CO, variable $Q_p:Q_s$, acidosis and need for inotropic support (227,228). The second stage, done at the time of the bidirectional cavopulmonary anastomosis at 3 to 6 months of age, includes the aortic reconstruction.

Despite remarkable improvements in the perioperative mortality of HLHS patients over the past several decades, there is still a high incidence of morbidity in the CICU, and these patients utilize significant resources. Institutions caring for these patients need to plan accordingly (229).

D-Transposition of the Great Arteries

This lesion is often diagnosed prenatally, and delivery should be in a referral center if possible. In the absence of a VSD and inadequate atrial-level shunting, PGE₁ is begun to maintain ductal patency and improve mixing to sustain adequate oxygenation. The approach to BAS is institution dependent, but $SpO_2 < 75\%$, $PaO_2 < 40$ mm Hg are indications for BAS, which can be done at the bedside with echo guidance or in the catheterization laboratory after tracheal intubation with appropriate sedation. Adequate atrial mixing is evident by echocardiography and heralded by immediate increase in oxygenation. Some institutions will electively perform BAS even if SpO_2 is acceptable with a PDA, then extubate the patient, wean off the PGE₁, allow the patient to feed, and schedule repair at 1 to 2 weeks of age. One study demonstrated that BAS is associated with preoperative strokes diagnosed by brain MRI, but studies from two other centers did not find this association (230–232). Preoperative $PaO_2 < 40$ mm Hg and delays in surgery beyond 6 days in these cyanotic patients were associated

Figure 20.13. Pathophysiologic considerations for patients with a single functional ventricle. (Reproduced from Diaz LK, Nicolson SC, Steven JM. Chapter 24: Anesthesia for the patient with a single ventricle. In: Andropoulos DB, Stayer SA, Russell IA, Mossad EB, eds. *Anesthesia for Congenital Heart Disease*. 2nd ed. Oxford, UK: Wiley-Blackwell, 2010:456–479, with permission.)

with preoperative brain white matter injury. Therefore, TGA patients with significant cyanosis after BAS should be repaired as soon as possible. Significant cyanosis before repair with a preductal SpO₂ significantly lower than postductal SpO₂ may indicate PH and may respond to inhaled NO.

Postoperatively after the arterial switch operation (ASO), understanding of coronary anatomy and details of the repair are important to glean from the surgeon's report. Echocardiography is used to assess ventricular function and any segmental wall motion abnormalities, important for diagnosis of coronary insufficiency from mechanical obstruction (233). Inotropic support in the form of milrinone, low-dose epinephrine, or dopamine is often necessary early in the postoperative period. Nitroglycerin is used in many centers to ensure maximal coronary artery dilation (234). Bleeding from extensive aortic suture lines may be an issue. Transthoracic left atrial catheters are used in many centers and maintaining adequate CO with low LA pressures is important, particularly in the patient with intact ventricular septum in whom there is often some degree of LV deconditioning. The majority of ASO patients have technically adequate repairs, acceptable ventricular function and progress rapidly toward weaning of inotropic and ventilator support in the first 24 to 72 hours. Ventricular dysfunction, ST-segment abnormalities, and ventricular arrhythmias are signs of a coronary artery problem that must be addressed urgently. When ASO is performed relatively late (at age 2 to 4 weeks or later) in the patient with intact ventricular septum, particular attention to LV function is necessary due to possible LV deconditioning.

Truncus Arteriosus

Preoperatively, low diastolic blood pressure from runoff into the pulmonary arteries can be the cause of coronary insufficiency and myocardial dysfunction or poor systemic perfusion that may cause renal or mesenteric ischemia the latter can be heralded by signs of necrotizing enterocolitis. As PVR decreases, these patients are increasingly tachypneic from pulmonary overcirculation. Room air spontaneous ventilation is often a prudent strategy as the patient will control their own minute ventilation. Diuretics are often needed, and tracheal intubation is utilized only for respiratory failure or significant hemodynamic instability. These patients should have repair as soon as possible during the first week of life if they exhibit signs of significant pulmonary overcirculation or decreased systemic perfusion.

Postoperatively, these patients are at risk for hemodynamic compromise from ventricular dysfunction, truncal valve insufficiency, and PH. An understanding of the status in the OR, including echo findings, is important to help direct early postoperative care. Significant inotropic support may be required, along with iNO if PH is an issue affecting CO. Bleeding from extensive suture lines in the aorta, right ventricle, and pulmonary arteries is common.

Total Anomalous Pulmonary Venous Return

The degree of obstruction to pulmonary venous return, including restriction of right-to-left flow at the atrial level, determines preoperative management. Severely obstructed patients require emergent surgery, and every effort should be directed toward the goal of instituting CPB as quickly as possible to provide adequate oxygenation and then proceeding with repair. With significant obstruction, increasing FiO₂ and lowering PVR with iNO is counterproductive; the increased pulmonary blood flow is met with fixed anatomic obstruction, resulting in worsening interstitial and pulmonary edema and paradoxically worsening pulmonary mechanics. In such cases, rapid transport to the OR is essential. In lesser degrees of

obstruction, surgery can be done semiselectively; diuretics are often effective at reducing pulmonary edema. TAPVR repair in infants is usually done with DHCA.

Postoperatively, ongoing PH is frequently problematic and these patients are often admitted to the CICU postoperatively with iNO. The period of maximum increase in PVR due to CPB occurs during the first 6 to 12 h, and adequate sedation and analgesia must be provided during this period. In addition, the small LV is often noncompliant, and heart rate may increase during the early postoperative period to maintain CO. After this time, straightforward two-ventricle TAPVR patients are often relatively stable and can be weaned from iNO, sedation, and ventilation over the next several days with vigilance for pulmonary hypertensive episodes. Complex TAPVR, including mixed lesions, single ventricle with heterotaxy and with additional lesions such as pulmonary atresia or aortic arch anomalies complicate the postoperative care and require frequent individualized adjustments of therapy. Often prolonged periods of mechanical ventilation and inotropic support are necessary.

Systemic-to-Pulmonary Artery Shunts

Preoperatively these patients are usually maintained on PGE₁ for ductal patency. Surgery is performed with a 3 to 4 mm PTFE graft from the innominate or right subclavian artery for pulmonary atresia or significant stenosis. Some centers will place a stent in a PDA with favorable anatomy (235). Surgical approach varies, with some centers preferring a median sternotomy, others a right thoracotomy. A sternotomy is done if CPB is necessary for reconstruction of pulmonary artery. A sternotomy has the advantage that the surgeon can ligate the PDA, leaving only one source of pulmonary blood flow. The PDA cannot be ligated from a right thoracotomy, and there will be two sources of pulmonary blood flow until the PDA closes. This often leads to pulmonary overcirculation. However, a shunt via the innominate artery often can provide excessive pulmonary blood flow. Placement of a shunt from the smaller right subclavian artery via thoracotomy will limit blood flow. These details must be communicated during the surgical hand-off, and the patient managed accordingly. Excessive pulmonary blood flow is heralded by high oxygen saturations even on low FiO₂ and low diastolic blood pressures. Coronary ischemia and cardiovascular collapse are possible. These are managed with manipulation of the FiO₂ and ventilation and with inotropic and vasopressor support to increase the systolic and diastolic blood pressure. This problem usually improves after 24 to 48 hours with closure of the PDA. The problem of excessive pulmonary blood flow is especially prevalent in small neonates under 2.5 kg, where even a 3.0-mm shunt may be relatively large. Downsizing the shunt may be necessary in some circumstances. Maintaining systolic blood pressure at 70 mm Hg or higher is desirable early in the postoperative course to promote pulmonary blood flow. Dopamine, epinephrine, or vasopressin is useful for this purpose. Low-dose heparin infusion is instituted in the first 6 to 12 hours postoperatively. Conversely, severe hypoxemia may be caused by mechanical obstruction of the shunt, PH, or systemic hypotension leading to decreased pulmonary blood flow. This situation must be investigated emergently by echocardiography. Maintaining high systolic blood pressure is crucial if shunt narrowing by thrombosis is suspected. Emergent revision of the shunt may be needed surgically. Alternatively, it is sometimes possible to dilate the shunt in the catheterization laboratory. Complete occlusion of a Blalock-Thomas-Taussig (BTT) shunt in a patient without other sources of pulmonary blood flow results in rapid hypoxemia and cardiac arrest. Resuscitation is instituted but shunt revision must be done immediately. These patients will often need a period of ECMO support after such an incident. Prevention

of shunt thrombosis with low-dose heparin and adequate systolic blood pressure and prevention of PH are key points.

Tetralogy of Fallot

Depending upon surgical results and institutional preference, most centers will perform complete tetralogy repair in infancy, including during the neonatal period for symptomatic RVOT obstruction or pulmonary atresia (236). However, some institutions will perform a systemic-to-pulmonary artery shunt in young infants, preferring to allow the patient to grow to 5 to 10 kg before complete repair (237). Repair in the young infant with pulmonary atresia or significant stenosis involves a Rastelli-type surgery with VSD closure RVOT muscle resection placement of an RV to PA valved conduit. Branch pulmonary arteries are repaired by pericardial or homograft patch if needed. A coronary artery branch from the left anterior descending coronary artery may be present near the site of right ventriculotomy, and coronary ischemia is possible if this structure is injured or distorted by the surgery. In small infants, a 3- to 5-mm ASD is left or created for an atrial level pop off because of the risk of RV systolic and diastolic dysfunction. This is an important piece of information that must be communicated during handoff from the surgical team, as this will often explain the early postoperative arterial desaturations. Older patients often undergo a transatrial transpulmonary repair of the VSD, RVOT resection, and limited incision across the pulmonary valve annulus with transannular pericardial patching if needed (238). Some surgeons will place a monocusp pulmonary valve made from the patient's own pericardium or synthetic material to minimize pulmonary insufficiency in the early postoperative period.

Postoperatively, neonatal TOF repair patients may require significant inotropic support, and be quite unstable early in their course with desaturation from atrial level shunting. Management of such patients can be helped with information gained from using a left atrial catheter. RAP is often increased due to restrictive RV physiology, and high filling pressures are often necessary. Bleeding may be a significant issue and tetralogy patients as a group are at the highest risk for postoperative JET, which can have profound hemodynamic significance and must be addressed promptly.

Ventricular Septal Defect, Atrioventricular Septal Defect

The majority of older patients with small VSD or partial or transitional AVSD undergo straightforward surgery, with little need for inotropic support and minimal bleeding and can be extubated in the OR or shortly after admission to the CICU. Smaller infants with large VSD or AVSD with PH, especially Trisomy 21 patients, require caution and a high degree of vigilance postoperatively for pulmonary hypertensive crises. These patients should have a period of at least moderate sedation, mechanical ventilation, and monitoring for PH crises, usually 12 to 24 hours, before weaning toward extubation. Because of the current practice of routine repair in early infancy in these patients, severe PH is encountered infrequently. When PH is a significant risk, iNO can be effective at preventing crises. Transthoracic pulmonary artery catheters infrequently are used because PAPs are likely to be elevated for days to weeks early after repair, limiting their utility. Bleeding risk is also much higher with these catheters (239,240).

Coarctation of the Aorta, Aortic Arch Hypoplasia, and Interruption

Patients with neonatal coarctation of the aorta, arch hypoplasia, or interruption may present with shock from inadequate

systemic perfusion, when the PDA closes in the first days to several weeks of life (241). PGE₁ infusion and resuscitation, inotropic support, mechanical ventilation, and recovery of end-organ injury should precede repair. Simple juxtaductal coarctation without arch hypoplasia or intracardiac defects is repaired via left thoracotomy, normally using extended end-to-end anastomosis. There is usually 15 to 30 minutes of aortic clamping without CPB. Blood pressure monitoring with an arterial catheter in the right upper extremity is necessary. Most neonates tolerate this surgery well, with minimal need for inotropic support. They are able to wean from mechanical ventilation in 24 to 48 hours after surgery. Older children will often be extubated in the OR. Vasodilators may be necessary in early postoperatively for blood pressure control. Because of the rare complication of paraplegia due to spinal cord ischemia from clamping above the level of the artery of Adamkovich at about the T9 level, all patients should be assessed for lower extremity movement as soon as possible after surgery. Renal or mesenteric ischemia is rare after a short period of crossclamping. The patient is normally cooled in the OR to 34°C to 35°C to afford spinal cord protection.

Significant aortic arch hypoplasia or interruption is repaired via median sternotomy and usually deep hypothermia with a period of DHCA lasting <30 minutes, or ACP. Intracardiac defects, that is, VSD, are repaired at the same time (242). These patients are at significant postoperative bleeding risk due to extensive aortic suture lines, and adequate blood products must be available for hemostasis early in the postoperative course. In addition, uncontrolled blood pressure will increase risk of significant bleeding or dehiscence of the aortic suture lines.

Hypertension is often observed after coarctation repair. The early phase is catecholamine-mediated and usually best treated with β -blocking agents such as esmolol or labetalol. The later phase is mediated by increases in angiotensin and is best treated with ACE inhibitors instituted 24 to 48 hours postoperatively.

Bidirectional Cavopulmonary Connection

The bidirectional cavopulmonary connection, also termed BDG anastomosis, is the common intermediate surgical procedure between the neonatal period and the completion of the total cavopulmonary anastomosis (Fontan operation). The Glenn procedure is performed now for virtually all single-ventricle lesions, normally at 2 to 6 months of age. The SVC is anastomosed to the right PA and the systemic to PA or RV to PA shunt is taken down. The pulmonary arteries are sometimes patch augmented, and any intracardiac issues, that is, significant AV valve regurgitation, or atrial septectomy, are addressed. If a simple BDG is performed, some centers will complete this procedure without CPB (243). Others will use CPB without aortic crossclamping. Intracardiac procedures necessitate at least some crossclamping and if the aortic arch must be repaired, that is, in residual coarctation or hybrid procedure for HLHS, the crossclamp period may be long. These details must be thoroughly communicated at the CICU hand-off from the OR team.

To be candidates for a BDG, PVR cannot be significantly elevated preoperatively. However, as noted above, in these patients, even subtle increases in PVR postoperatively, sometimes with normal PAP, can complicate recovery. In addition, if the patient is hyperventilated, cerebral blood flow will decrease significantly, thereby decreasing SVC flow, thus pulmonary blood flow, and the patient will become hypoxemic (172,173) (Fig. 20.14). PaCO₂ goals early after the BDG are usually 40 to 50 mm Hg, while maintaining pH above 7.30. This will promote cerebral and pulmonary blood flow. If the patient has undergone uncomplicated simple BDG, early extubation in

Figure 20.14. The cardio-cerebral-pulmonary circulation after cavopulmonary anastomosis. The relatively large brain of the young infant carries a large percentage of the cardiac output. Hyperventilation will decrease PaCO_2 , constricting the cerebral arterioles and decreasing cerebral blood flow. This in turn decreases superior vena cava flow, decreasing pulmonary artery flow, which will lead to decreased systemic arterial oxygenation. (Figure courtesy of Stephen A. Stayer.)

the OR or CICU is desirable. Positioning the patient in semi-Fowler's position with the head elevated 30 to 45 degrees, and positioned in the midline, will improve cerebral venous drainage and oxygenation. Measurement of transpulmonary pressure gradient, using a small right internal jugular catheter in the SVC, and a catheter in the common atrium, is helpful to guide therapy in the early postoperative period. Some centers use nitroglycerin infused into the SVC catheter as a NO donor for pulmonary vasodilation. The BDG patient who is desaturated can have impedance to pulmonary blood flow from PH, inadequate intravascular volume, poor systemic ventricular

function with or without AV valve regurgitation or stenosis at the surgical anastomosis of SVC and PA. Hypovolemia or anemia can also cause desaturation. PA and atrial pressures and transpulmonary pressure gradient, along with echocardiography are used to elucidate the cause. A summary of the hemodynamic findings and etiologies in the postoperative BDG patient is presented in Table 20.10. Many of these infants are quite irritable and hypertensive after the BDG. This is thought to represent headache from cerebral vascular attempts to reset conditions by autoregulation because of the now higher SVC pressures after the surgery. Analgesics such as morphine, acetaminophen, ibuprofen, and ketorolac are effective. The adjustment of cerebral circulation is accompanied by diminution of these symptoms, usually after 48 to 72 hours.

Fontan Completion

Total cavopulmonary connection is the intended final stage of palliation for most single-ventricle patients. Preoperatively, determination of the anatomy (right or left systemic ventricle), ventricular function, degree of AV valve regurgitation, and presence of pulmonary arteriovenous malformations causing desaturation are important. The surgical procedure itself has undergone many modifications since its original description by Fontan and Baudet in 1971 (244) (Fig. 20.15). In the current era, the extracardiac Fontan consisting of an 18- to 20-mm PTFE graft sewn to the inferior vena cava, with the other end anastomosed to the underside of the right PA, is favored in many centers (245). This can be done without aortic crossclamping or in some cases even without full CPB (246). The lateral tunnel Fontan is also frequently performed in which the atrium is opened and a PTFE patch is sewn inside to create a tunnel for blood flow from the IVC through the top of the atrium to the PA. A fenestration is sometimes created from the Fontan circuit to the left atrium, which is a 3- to 5-mm communication allowing right-to-left shunting, which lowers Fontan circuit pressure and allows greater systemic CO at the expense of some arterial desaturation (247). It should be noted that many Fontan completions, even without fenestration, are not fully saturated due to the opening of the coronary sinus into the left atrium. The details of the surgery, as to what type of Fontan connection, presence of a fenestration, and use of CPB and associated procedures, must be clearly communicated.

TABLE 20.10 Hemodynamic Findings and Etiologies in the Postoperative Bidirectional Cavopulmonary Anastomosis Patient

Profile	PAP (mm Hg)	LAP (mm Hg)	TPG (mm Hg)	SaO ₂ %	Etiology
Normal	10–15	2–6	<10	80 ± 5	Ideal anatomy and physiology
Elevated PAP	>15	2–6	>10	80 ± 5	High PVR; PA or PV obstruction
Elevated LAP	>10–15	>5–8	<10	80 ± 5	Ventricular systolic/diastolic dysfunction; sub-AS; AVVR; tamponade
Cyanosis	10–15	2–6	<10	<75	Decreased CBF; PV desaturation; decompressing veins; hypovolemia; anemia

PAP, pulmonary artery pressure measured in superior vena cava; LAP, left or common atrial pressure; TPG, transpulmonary pressure gradient; PVR, pulmonary vascular resistance; PV, pulmonary vein; AS, aortic stenosis; AVVR, atrioventricular valve regurgitation; CBF, cerebral blood flow.

Figure 20.15. Lateral tunnel Fontan (left) and extracardiac Fontan (right). A fenestration can be placed with either of these configurations.

Because the total cavopulmonary connection results in the absence of a pulmonary ventricle to actively pump blood into the lungs, flow into and through this circuit depends in large part on negative intrathoracic pressure creating a gradient from the extrathoracic systemic venous return to the cavae and heart. Therefore, positive pressure ventilation will decrease venous return and CO. Many centers will extubate the Fontan patient in the OR by limiting the dose of opioids to promote this venous return and CO. This requires a patient who is hemodynamically stable on low doses of inotropic support, in normal sinus rhythm or other AV synchrony, not bleeding and making sufficient respiratory effort with adequate gas exchange. In the absence of these conditions, the trachea should be left intubated for CICU transfer.

The Fontan patient is highly dependent on adequate filling volume in the total cavopulmonary connection during the early postoperative period to maintain CO. In the ventilated patient, the effect of the positive pressure can be overcome

with higher filling pressures, that is, 15 to 20 mm Hg. Atrial filling pressures must be maintained at an adequate level. For this reason, an atrial catheter is often placed in Fontan patients. A key point in the early postoperative period is to not get behind in volume replacement. Bleeding from repeat sternotomy and large pleural and mediastinal tube output from increased right-sided pressures often result in significant need for volume replacement. Inotropic support in the form of milrinone and low-dose epinephrine or dopamine is often needed in the early postoperative course. Extubation should be accomplished as early as possible. Close attention to cardiac rhythm and providing AV synchrony with pacing if needed and treating atrial arrhythmias are very important to maximize CO. Nonfenestrated patients especially are prone to high Fontan pressures and pleural effusions. Conversely, they will benefit the most from early extubation. Differential diagnosis of abnormal post-Fontan hemodynamic states is presented in Table 20.11.

TABLE 20.11 Hemodynamic Findings and Etiologies in the Postoperative Fontan Patient

Profile	PAP (mm Hg)	LAP (mm Hg)	TPG (mm Hg)	Systolic BP (mm Hg)	SaO ₂ %	Etiology
Normal	10–15	2–6	<10	85–95	95 ± 5	Ideal anatomy and physiology
Decreased PAP and LAP	8–10	0–4	<10	<80	90 ± 5	Hypovolemia
Elevated PAP	>15	2–6	>10	80 ± 5	90 ± 5	High PVR; PA or PV obstruction
Elevated LAP	>10–15	>5–8	<10	80 ± 5	90 ± 5	Ventricular systolic/diastolic dysfunction; AV dissociation; AVVR; tamponade
Cyanosis	10–15	2–6	<10	85–95	<85%	Excessive fenestration size or baffle leak; PV desaturation; decompressing veins; hypovolemia; anemia

PAP, pulmonary artery pressure measured in superior vena cava; LAP, left or common atrial pressure; TPG, transpulmonary pressure gradient; PVR, pulmonary vascular resistance; PV, pulmonary vein; AV, atrioventricular; AVVR, atrioventricular valve regurgitation.

Other Left-Sided Obstructive Lesions

Aortic stenosis, mitral stenosis, and Shone complex present with a myriad of anatomic variation. The preoperative status of the patient, including ventricular dysfunction and/or hypertrophy and any medications including β -blockade, must be reviewed. Details of the surgery, whether valve repair with subaortic resection or valve replacement, must be communicated. Postoperative transesophageal echocardiographic data should be understood. Residual lesions, that is, stenosis or regurgitation, should be reviewed. With postoperative normal or hyperdynamic left ventricular function, relief of mechanical obstruction will often result in a hypertensive patient, and β -blockade with esmolol should be considered along with other vasodilator therapy, that is, nitroprusside or calcium channel blocker such as nicardipine in older patients. It is important to control blood pressure, as there will frequently be a long aortic suture line and bleeding or dehiscence can accompany uncontrolled high blood pressure. Patients with poor ventricular function may require significant inotropic support. A left atrial catheter is very helpful in these patients to assess the degree of filling of the left ventricle and any residual mitral stenosis or regurgitation.

Other Right-Sided Obstructive Lesions

Pulmonary atresia with intact ventricular septum is a complex lesion with perioperative and catheterization management dependent on details such as the presence of an RVOT, and a reasonably sized RV with thin pulmonary valve leaflets that can be perforated in the catheterization laboratory with radiofrequency energy (248). Other important considerations are the status of the coronary arteries, whether there is proximal coronary artery atresia and right ventricular dependent coronary sinusoids. These patients may be admitted postprocedure to the CICU having undergone one or a combination of RV perforation in the catheterization laboratory or OR, BT shunt, or ductal stenting, and atrial septectomy or septostomy. The details of the procedure should be clearly communicated and CICU care directed accordingly. A common scenario is the creation of RVOT blood flow and then discontinuing PGE₁ postprocedure to assess adequacy of pulmonary blood flow. Vigilance for hypoxemia necessitating restarting of PGE₁ accompanied by echocardiographic evaluation is important.

Pulmonary atresia with VSD and multiple aortopulmonary collaterals (MAPCAs) is another complex lesion, with multi-level preoperative decision making and considerable practice variation among centers. Approaches vary from complete repair via median sternotomy with extensive bilateral unifocalization of MAPCAs, placement of RV to PA conduit, and VSD closure in infants under 6 months (249) to a staged approach that may include thoracotomy for one-sided unifocalization with BT shunt, or central aortopulmonary shunt as a first procedure. Then, thoracotomy on the opposite side may be done for unifocalization followed by a third procedure for a Rastelli-type repair as the intended final stage (250,251). The preoperative anatomy, history of surgery, status of the pulmonary vascular bed, and presence of a residual VSD or ASD are very important to understand.

Ebstein anomaly of the tricuspid valve patients may present to the CICU pre- or postoperatively. Infants with severe malformation are significantly ill with cyanosis and may have SVT or other atrial arrhythmias. The severe TR often results in functional pulmonary atresia. Some patients have anatomic pulmonary atresia. With severe disease, the massive increase in RV size and increase in RV pressure causes impingement on the LV. The interventricular septum is displaced right to left; LV filling and stroke volume are compromised, leading to low

systemic CO. Even after surgery such as valve repair or BT shunt to provide pulmonary blood flow, they will require significant cardiopulmonary support (252).

Tricuspid atresia patients may present in the neonatal period after a BT shunt for pulmonary atresia or stenosis or a PA band for unobstructed pulmonary blood flow. Some patients may have mild-to-moderate pulmonary stenosis and need no intervention in the neonatal period. The BDG usually is performed at 3 to 6 months of age.

Cardiac Transplantation

The preoperative status of the transplantation patient must be thoroughly reviewed and understood, particularly in reference to PH, which can complicate the postoperative course. Intraoperatively, the donor organ ischemic time also should be as short as possible, but given issues with transport of the organ or a complex transplantation procedure such as for cyanotic CHD, ischemic times may be longer. Generally speaking, ischemic times <5 hours are desirable with better myocardial function in the early postoperative period. Details about the donor heart, such as circumstances of the donor's death, cardiac function, level of inotropic support, and any defects such as ASDs are important. Normally, the donor body weight should be 80% to 120% of the recipient's weight. When a small donor heart is placed in a recipient with PH, increased potential for RV dysfunction exists. Additional right ventricular support in the form of milrinone, iNO, or occasional RV assist device may be required in these patients (253). It is also important to understand whether the patient has elevated panel reactive antibodies or a positive crossmatch with the donor heart. In such cases, intraoperative or postoperative plasmapheresis may be instituted to minimize risk of early rejection. ABO-incompatible transplants in infants are increasingly common (254).

The denervated heart after transplantation will not respond to parasympathetic inputs. Therefore, vagolytic agents such as atropine and pancuronium will not increase the heart rate. Many institutions use low-dose isoproterenol immediately postoperatively to maintain heart rate, as there is often slowing of SA node discharge over the initial hours in the ICU. Atrial pacing wires are also placed, and this is another alternative for treatment of slowing HR. Direct-acting adrenergic agents such as epinephrine are also effective. Early in the postoperative period, the same considerations for bleeding, inflammatory response, and pulmonary dysfunction as for standard CHD surgery are followed. It is very important to maintain the patient's corticosteroid, other immunosuppressive agents, and antibiotic regimens exactly according to protocol and schedule and to maintain strict infection prevention precautions in these patients (255). Uncomplicated transplants, that is, first-time sternotomy, no PH, good donor heart function, and minimal bleeding can usually be extubated 12 to 24 hours postoperatively. Transplants complicated by bleeding, PH, complex reconstructions, or in small infants may require prolonged postoperative ventilation and inotropic support.

CENTRAL NERVOUS SYSTEM ISSUES

Sedation and Analgesia

Sedation and analgesia are daily considerations for most CICU patients. Institutional approaches and protocols for sedation and analgesia are highly desirable to standardize care as much as possible and decrease the incidence of undertreated pain and patient distress from anxiety. The ventilated postsurgical

patient will require significant doses of analgesic and sedative drugs, most often in the form of opioids (morphine, fentanyl), which should be given as continuous infusions or on a scheduled basis after major surgery. Similarly, sedation for anxiolysis and to prevent awareness is often provided by benzodiazepines (midazolam, lorazepam). Muscle relaxation is rarely indicated, except where patient movement or coughing will interfere with care, that is, ventilation. Patients with severe lung disease, or at high risk for PH crises who are treated with ECMO or other mechanical support, are often in need of continuous muscle relaxation. A peripheral nerve stimulator, placed over the ulnar nerve, should be used and state of neuromuscular blockade assessed and titrated frequently. Administration of unnecessarily large doses of sedatives, analgesics, and muscle relaxants can lead to a polyneuropathy syndrome characterized by prolonged muscular weakness that may significantly complicate weaning from support (256,257). The minimum effective doses necessary to achieve desired sedation and analgesia should be used. A pain and sedation scale or score with clear goals for each patient, is administered at regular intervals by the bedside nursing staff, and should be part of each institution's protocol (258). Older extubated patients often do very well with patient-controlled analgesia. Neuraxial anesthesia, with continuous local anesthetic infusions with or without opioids, given through thoracic epidural or paravertebral catheters, is often very effective for thoracotomy pain. Parental presence, nursing interventions, and the Child

Life Team are all very important nonpharmacologic strategies for the daily pain and distress that accompany a CICU stay.

Continuous infusions of sedative agents may be necessary for patients who are difficult to sedate. Propofol should never be used for this purpose in children because of its clear association with propofol infusion syndrome that occurs when it is used in large doses over a long time. This syndrome is characterized by mitochondrial failure, severe myocardial dysfunction, acidosis, and cardiovascular collapse leading to death (259,260). The newer IV agent, dexmedetomidine, a centrally acting α_2 antagonist agent with actions similar to clonidine has gained increasing use in CICUs because of its ability to sedate the patient, its additive effects with opioids, its ability to preserve respiratory drive, and its hemodynamic effects including lowering blood pressure and heart rate (261). This agent generally should not be used in infants and in patients with bradycardia or those who are hemodynamically unstable. AV block has been described with this agent (262–264). Despite its potential respiratory benefits, dexmedetomidine was not shown to facilitate early extubation in a recent retrospective review (265). Additional agents that may be used include ketamine, especially for painful procedures barbiturates and chloral hydrate. Table 20.12 summarizes major classes of sedative and analgesic drugs, doses, and side effects.

Tolerance; dependence; and a withdrawal syndrome to opioids, benzodiazepines, and other drugs are often observed in CICU patients who receive significant doses and have long ICU

TABLE 20.12 Sedative and Analgesic Drugs

Drug	Class	Dosing	Indications	Comments
Fentanyl	Opioid	Bolus: 1–2 $\mu\text{g/kg}$ Infusion: 1–10 $\mu\text{g/kg/h}$	Analgesia	Chest wall rigidity with rapid bolus; rapid tolerance with infusion
Morphine	Opioid	Bolus: 0.05–0.1 mg/kg Infusion: 0.025–0.1 mg/kg/h	Analgesia	
Methadone	Opioid	0.1–0.2 mg/kg Q8–12h	Analgesia; opioid tolerance	Use for opioid wean protocol
Midazolam	Benzodiazepine	Bolus: 0.025–0.1 mg/kg Infusion: 0.05–0.1 mg/kg/h	Amnesia, sedation, anxiolysis	Rapid tolerance with infusion
Lorazepam	Benzodiazepine	Bolus: 0.025–0.1 mg/kg q 4h	Amnesia, sedation, anxiolysis	
Ketamine	Arylcyclohexylamine	Bolus: 1–2 mg/kg Infusion:	Analgesia, sedation	Hallucinations, dysphoria, excessive salivation, tachycardia
Propofol	Imidazole derivative	Bolus: 1–3 mg/kg Infusion: 100–200 $\mu\text{g/kg/min}$ for procedural sedation	Procedural sedation	Do not use for prolonged ICU sedation, i.e., >4 h
Dexmedetomidine	Central α_2 agonist	0.3–0.7 $\mu\text{g/kg/h}$	Sedation; some analgesia	For short-term ICU sedation; bradycardia and heart block in infants
Acetaminophen	Inhibits prostaglandin synthesis	10–15 mg/kg q 6h	Analgesia	Do not use with significant hepatic disease
Ketorolac	Nonsteroidal anti-inflammatory agent (cyclo-oxygenase-1 and 2 inhibitor)	0.5 mg/kg q 6h; max 30 mg; do not administer for more than 48–72 h	Analgesia	Inhibition of platelet function: bleeding. Renal impairment

All doses are intravenous; see text for details.

Figure 20.16. Principles of NIRS. The sensor is placed on the forehead, and a light- or a laser-emitting diode uses 2 to 4 wavelengths of near infrared light at 700 to 1,000 nm. Oxy- and deoxyhemoglobin have distinct light absorption spectra, and the device calculates the oxyhemoglobin saturation using a modification of the Beer-Lambert Law. Regional oxygen saturation (rSO_2) is reported. Since arterioles, veins, and capillaries are all in the light path, rSO_2 is a venous-weighted oxygen saturation of a tissue sample volume in the frontal cerebral cortex. A subtraction algorithm using surface and deep photodetectors removes signal from shallow tissues, that is, skin, skull, and dura. (Figure courtesy of Covidien-Somanentics Corp.)

stays (266). Risk for this syndrome is generally higher with continuous infusions of large doses of potent synthetic opioids, that is, fentanyl and infusions of short-acting benzodiazepines, that is, midazolam. If these therapies are necessary early after CICU admission, their need should be evaluated daily, minimum effective doses used, and instead of continually escalating doses, adding long-acting scheduled doses of opioids, that is, morphine or methadone, and benzodiazepines, that is, lorazepam, should be considered. Low-dose naloxone infusion may be effective at preventing tolerance syndromes (267). Dexmedetomidine and clonidine have opioid-sparing effects (268). Also, intravenous acetaminophen, ibuprofen, or ketorolac are now available and should be considered for their opioid-sparing effects when no contraindications exist. Patients should be assessed for withdrawal syndromes using the various semi-objective grading scales and if established, a plan to gradually wean the sedative and analgesic drugs, that is, 5% to 10% per day, and substitute long-acting drugs (methadone and lorazepam) or drugs from other classes (barbiturates, transdermal clonidine patch) for withdrawal symptoms. Consultation with an acute pain service expert is recommended for difficult cases.

CNS Injury: Etiologies, Prevention, Evaluation, Treatment

The recognition that patients with CHD who have undergone complex or moderately complex surgery have a significant incidence of long-term, mostly subtle neurodevelopmental problems by the age of school entry has focused attention on the perioperative period as a potential cause of brain injury. In the modern era, gross injuries such as large strokes, seizures, choreoathetosis, and coma are very rare. A myriad of causes of brain injury and abnormal neurodevelopment exists. A recent finding has been that the brains of patients with complex CHD who undergo operation in the neonatal period are very often immature, that is, the full-term infant with complex CHD often has the brain with the morphologic and microcellular characteristics of a premature infant of 32 to 34 weeks' gestational age (269,270). In turn, this brain immaturity leads to higher incidence of brain injury both pre- and postcardiac surgery (232). The falloff in brain growth and maturation begins in the third trimester, and has raised the issue of whether delivery, or CPB surgery before term, is advisable (271,272).

Perioperative etiologies of brain injury include prolonged hypoxemia before repair (231), BAS in some series (230), and prolonged DHCA over about 45 minutes. (206). In addition, hematocrit on CPB below 24% (273) rapid cooling, and α stat management have also been associated with early evidence of CNS injury (207,274). The availability of NIRS to monitor

regional cerebral oxygen saturation (rSO_2) has led to the widespread use of this real-time monitor of cerebral oxygenation in the CICU on many high-risk postoperative patients. These include neonates undergoing complex surgery, patients on mechanical support or older high-risk patients. Prolonged low rSO_2 has been associated with new postoperative brain MRI injury (275,276), need for ECMO and death in HLHS patients (277), and long-term MRI change and lower neurodevelopmental scores (278). To date, there are no published controlled trials of NIRS monitoring and intervention for CHD conclusively demonstrating that this monitoring with intervention protocols improves outcome. However, accumulating evidence of the use of this monitor to maintain a goal rSO_2 (normally $>50\%$) demonstrates its important benefits. In the CICU, NIRS monitoring can help direct therapies to increase oxygen delivery to the brain, including ventilator maneuvers, increasing CO, and hemoglobin. For example, unnecessary or inadvertent hypocarbia significantly affects cerebral blood flow in infants and leads to low rSO_2 (279). In addition, therapies decreasing cerebral oxygen consumption by lowering temperature adding sedative agents or treating seizures, can be directed with NIRS monitoring. The rSO_2 is a noninvasive surrogate for SvO_2 as well and can thus be used to help direct therapy to optimize global oxygen delivery (33). Figure 20.16 illustrates basic principles of NIRS and Table 20.13 summarizes maneuvers to increase rSO_2 . (For a complete discussion of CNS outcomes in CHD, please see Chapter 74.)

THE RENAL SYSTEM

Renal dysfunction is a common problem in CICU patients and frequent causes include LCOS, ischemia from long CPB times, postarrest injury, nephrotoxic drugs, congenital renal malformations, and hemolysis-induced tubular dysfunction from elevated plasma-free hemoglobin. Maintenance of adequate urine output to meet the fluid balance goals for each patient is important. Diuretic therapy, most commonly furosemide, is used for almost all postoperative patients to promote excretion of excess tissue fluid. Furosemide infusion can be an effective approach to the patient in need of maximal diuretic treatment. The incidence of renal dysfunction after congenital heart surgery in the modern era is about 20%, defined as at least a 50% increase in serum creatinine postoperatively (280). Diagnosis is made by noting increased serum creatinine and blood urea nitrogen, decreased urine output, and decreased calculated GFR. Renal ultrasound, including assessment of renal blood flow, may be a useful diagnostic

TABLE 20.13 Measures to Increase Regional Cerebral Oxygen Saturation (rSO₂)

Measures to increase oxygen delivery	
Oxygenation	Increase FiO ₂ ; other means to improve oxygenation
Ventilation	Decrease minute ventilation to increase PaCO ₂
Cardiac output	Volume infusion
	Inotropic, vasodilator support
Oxygen-carrying capacity	Increase hemoglobin by transfusion; diuresis
Relieve SVC obstruction	Head in midline; elevate HOB 30 degrees
Increase cerebral perfusion pressure	Treat hypotension—Increase blood pressure with vasopressors
Measures to decrease oxygen consumption	
Temperature	Cool brain/body temperature to 35°C–36°C
Sedation	Sedate patient to decrease CMRO ₂
Seizures	Treat seizures to decrease CMRO ₂

Measures to increase regional cerebral oxygen saturation (rSO₂). rSO₂ < 50%, or >20% relative below baseline, is a usual indication for treatment. Example: baseline rSO₂ = 65%, a decrease to 52% or lower is treated. SVC, superior vena cava; HOB, head of bed; CMRO₂, cerebral metabolic rate for oxygen.

modality. Temporary renal dysfunction heralded by increase in creatinine and decreased urine output caused by the surge in antidiuretic hormone (ADH) as part of the stress response to major surgery is common in the first 24 to 72 hours. Table 20.14 displays the pediatric RIFLE (pRIFLE), a commonly used scoring system for renal injury in pediatrics (280). When bleeding subsides and hemodynamic stability is achieved, diuretics are often added 12 to 24 hours after admission to the ICU.

Renal Replacement Therapy

The incidence of renal failure requiring renal replacement therapy after CHD surgery is very low, estimated at 1% to 3%, although its precise incidence is difficult to classify (280,281). Peritoneal dialysis is normally used in infants, and the catheter can be inserted at the bedside by the surgeon in the ICU. Normally, hourly cycles of 10 mL/kg of 1.5% to 2.5% Dianeal with 45- to 50-minute dwell time and 10-minute drain time

TABLE 20.14 The Pediatric RIFLE Criteria

Category	GFR Criteria	Urine Output Criteria
Risk	Increased creatinine 1.5 times baseline, or GFR decrease >25%	UO < 0.5 mL/kg/h × 6h
Injury	Increased creatinine 2.0 times baseline, or GFR decrease >50%	UO < 0.5 mL/kg/h × 12h
Failure	Increased creatinine 3.0 times baseline, or GFR decrease >75%	UO < 0.5 mL/kg/h × 24h, or anuria × 12h
Loss	Persistent acute renal failure = complete loss of renal function >4 weeks	
End-Stage Renal Disease	Persistent renal failure = complete loss of renal function >3 months	

GFR can be estimated by the Schwartz method: This equation may not provide an accurate estimation of creatinine clearance for infants <6 mo of age or for patients with severe starvation or muscle wasting.

$eGFR = (k \times \text{Height (cm)}) / \text{Creatinine (mg/dL)}$

where: eGFR = estimated GFR; calculated in mL/min/1.73 m²

k = constant of proportionality that is age-specific:

<1 y preterm: 0.33

<1 y full-term: 0.45

1–12 y: 0.55

>12 y female: 0.55

>12 y male: 0.7

GFR, calculated glomerular filtration rate; UO, urine output.

are very effective at removing excess fluid and balancing electrolyte values, for example, hyperkalemia. Close attention must be paid to hemodynamic and ventilatory status during infusion and draining of peritoneal dialysis fluid the first several cycles in small infants. Some programs routinely place peritoneal dialysis catheters in the OR after complex neonatal and infant surgery (282–284). The catheter is placed via the anterior mediastinum in front of the diaphragm for access to the peritoneal cavity or the catheter can be placed via a small supraumbilical incision and positioned from the incision near the diaphragm. This catheter is easily removed several days postoperatively. Peritoneal dialysis is instituted in the ICU soon after admission to achieve optimal fluid balance during the period of time when kidneys are avidly retaining fluid due to the ADH surge. In addition, mediators of inflammation are filtered in the dialysate reducing plasma levels of these small molecules and possibly reducing the severity of the inflammatory response.

Other forms of renal replacement, such as continuous venovenous hemofiltration continuous arteriovenous hemofiltration or hemodialysis, are reserved for larger patients whose blood vessels can accept the large catheters required for such therapies (285). Patients treated with ECMO or acute VAD therapy normally have a hemofilter placed in the circuit to augment native renal function and to fine tune fluid and electrolyte balances.

FLUIDS, ELECTROLYTES, AND NUTRITION

Intravascular volume and total body fluid status are high-priority issues daily for CICU patients. Most immediate postoperative patients are treated with less than maintenance daily fluid administration, that is, 50% of maintenance levels, with 5% or 10% dextrose and 0.2% to 0.45% normal saline. Potassium is not added to IV fluids initially. Bolus isotonic crystalloids, 5% albumin, or blood products are utilized in the early postoperative period to replace intravascular volume. Fluids are liberalized after 24 to 48 hours and those patients who are extubated and have normal gastrointestinal function will resume feeding shortly thereafter. Frequent measurement of electrolytes and maintenance of normal ranges for serum sodium, potassium, ionized calcium and magnesium are important to optimize end-organ function. Hypokalemia is frequent in patients receiving diuretic therapy and IV replacement over 1 to 2 hours is common. Hyperkalemia is treated first by removing any potassium from IV fluids and then increasing pH with bicarbonate, administering calcium chloride, and giving insulin to promote movement of K⁺ into cells. Kayexelate, a potassium-binding resin, is given per rectum. Hemodialysis is rarely necessary in persistent hyperkalemia. Hyponatremia is a common finding with diuretic therapy; reducing diuretic doses and decreasing the amount of free water intake are the usual approaches. In severe cases, that is, serum sodium <120 mEq/L with seizures, 3% sodium chloride may be necessary, although care must be taken not to correct the serum sodium faster than 10 mEq/L per 24 hours. Hypernatremia is uncommon, but increasing free water and decreasing sodium intake is the usual treatment.

Nutrition in critically ill patients in the CICU is a central issue, and adequate caloric intake is necessary to prevent protein catabolism, maintain energy stores for optimal cardiopulmonary function, promote wound healing, and prevent infection (286). Early complex postoperative patients are given standard IV fluids for 24 to 48 hours and if the GI tract cannot be used for early feeding, central parenteral nutrition should be instituted, increasing dextrose, amino acids, and intralipid infusions to meet goals for calories, protein, and

lipid administration. The gut should be used if at all possible, starting with small-volume continuous feeds of breast milk, fortified if necessary or with age and medical condition appropriate formula. Trophic levels of feeds will prevent involution of intestinal villi and promote higher success rates when full feeds are instituted. The recognition that infants having major cardiac surgery, particularly the Norwood Stage I palliation and other major aortic arch reconstruction, have a significant incidence of recurrent laryngeal nerve injury that affects vocal cord function (10% to 25%) along with a significant incidence of gastroesophageal reflux (GER) (48% to 59%) and aspiration (24% to 35%) (287) has led to institution of refeeding protocols in many centers. This involves an assessment of vocal cord function by nasoendoscopy, assessment of coordination of sucking and swallowing capability by an infant feeding specialist, and possibly barium swallow. Nasogastric or nasoduodenal feeds can be instituted if necessary in cases of vocal cord dysfunction and/or reflux. Persistent dysfunction of vocal cords and GER is an indication for placement of a gastrostomy tube, either surgically or by percutaneous endoscopic gastrostomy. Fundoplication is done less often but can be done via open surgical incision or laparoscopically. Another cause of feeding problems can be intestinal malrotation, frequently seen in patients with heterotaxy syndrome, and a Ladd procedure may be needed in these patients (288,289). Small infants with single-ventricle anatomy are particularly prone to feeding problems, and ICU care is usually necessary after abdominal surgery. Figure 20.17 outlines one approach to refeeding neonates after complex cardiac surgery.

Although not a feeding problem per se, chylothorax often becomes evident when the infant begins full feeding with regular formula and pleural effusion becomes evident on chest radiograph or chylous fluid begins draining from any of the chest tubes. Disruption of the thoracic duct or other lymphatics during surgery can lead to chylothorax, which can significantly complicate the postoperative course. Diagnosis is made by observing a high lymphocyte count and chylomicrons in the fluid. Treatment is initiated by stopping oral intake and starting total parenteral nutrition. When the drainage decreases significantly and is no longer chylous, cautious refeeding with nonfat containing formulae is reinstituted. This therapy may be necessary for weeks afterward until drainage stops. Persistent chylothorax can be treated by continuous infusion of the somatostatin analog octreotide, at 25 to 100 µg/kg/day for 3 to 7 days. Pleurodesis with mechanical methods, talc, or doxycycline is also used for persistent chylothorax. This procedure is extremely painful, initiates a significant inflammatory response, and is not often used. Ligation of the thoracic duct and oversewing of leaking lymphatics is sometimes necessary (290,291).

Glycemic Control

In recent years, an association between hyperglycemia and poor outcomes in ICU patients, particularly in the adult population, has been noted and subsequently an attempt to control glucose concentrations has been made in an attempt to improve these outcomes. The problems with this approach included the fact that it was very difficult to determine whether the hypoglycemia was the cause or the effect of the conditions that led to poor outcomes. In the neonatal and infant cardiac surgery population, hyperglycemia (serum glucose above 180 mg/dL) was not associated with an increased short-term morbidity in one study (292); however, in other studies, either low serum glucose (average below 110 mg/dL) or high serum glucose (average >145 mg/dL, or peak >250 mg/dL) were associated with early morbidity and mortality (293). Longer-term

TCH Evidence-Based Outcomes Center Clinical Algorithm for Feeding the Neonate Post-Cardiac Surgery

Figure 20.17. Suggested refeeding algorithm for neonates after cardiac surgery. ENT, ear, nose, and throat surgeon; OT, pediatric occupational therapy feeding specialist; EBM, expressed breast milk; RD, pediatric registered dietician; G-tube, gastrostomy tube; NG, nasogastric.

neurodevelopmental outcomes are not affected by hyperglycemia in the perioperative period for infant cardiac surgery (294,295). Both adult (296) and pediatric studies of tight glycemic control (target 81 to 108 mg/dL) versus standard therapy (target <180 mg/dL) demonstrated increased complications, most particularly hypoglycemia, and even death, with tight control (297). Clearly more data are needed in this area. In practice, a target glucose of 80 to 200 mg/dL in most CICU patients is adequate, and short-lived elevations above 200 mg/dL are common perioperatively, particularly if corticosteroids are used. These elevations are normally self-limited and do not necessitate insulin therapy; limiting the glucose infusion rate is sufficient. Insulin therapy is only used for persistent elevations in serum glucose above 300 mg/dL or when osmotic diuresis is complicating fluid therapy. Investigating and treating the underlying cause is important.

INFECTION IN THE PCICU

Prevention of Infection

The PCICU is at particularly high risk for nosocomial infection because of the invasive procedures, and many indwelling vascular catheters and the often-abnormal immune systems of the patients (298). Strict attention to preventing infection by common measures such as hand washing between every patient contact, disinfecting stethoscopes and other equipment and isolation of known or potentially infective patients is of critical importance. In addition, strict adherence to protocols for sterile insertion and maintenance of central venous catheters and protocols to prevent VAP has dramatically reduced such complications in units where they have been implemented (299). For each CICU patient, the treatment team must assess daily whether each indwelling catheter, or the endotracheal tube is necessary, how long it has been in place, whether infection is suspected, what the anticipated duration of placement is, and plans for its removal or replacement. Indwelling catheters and tubes should be removed as soon as possible.

Diagnosis and Treatment: Catheter-Related, Bloodstream, Pulmonary, Urinary, Wound Infections

The signs and symptoms of infection in CICU patients are myriad, and a high index of suspicion necessary in these patients. Fever or hypothermia, leukocytosis, hemodynamic or respiratory compromise, coagulopathy or failure to progress in the expected course of illness are common accompaniments of significant infection. A thorough examination, cultures of blood, endotracheal secretions, urine and imaging studies such as echocardiography to evaluate whether a vegetation is present, are necessary in suspected infection. Empiric antimicrobial therapy, removal of possibly infected catheters, and careful monitoring are first steps in treating significant infection. Therapy is narrowed and promptly directed specifically at any organisms that grow from cultures. Complex patients, that is, infected patients on mechanical support, benefit from consultation by the infectious disease service.

ENDOCRINE ISSUES

Adrenal Insufficiency and Corticosteroids

Some patients in the PCICU experience an acquired adrenal insufficiency from their critical illness or after suppression from chronic steroid administration. In patients suspected of

having adrenal insufficiency, a cosyntropin stimulation test can be done. Nonresponders will frequently benefit from a course of hydrocortisone with improved hemodynamic performance due to increased sensitivity to catecholamines (300,301). Patients with ongoing high inotropic requirements should be suspected of having this acquired adrenal insufficiency. Treatment with hydrocortisone will significantly reduce inotropic requirements in these patients within 6 to 12 hours.

Hypothyroidism

There is a decreased conversion of T4 to T3 after CPB in children, and hypothyroidism may accompany major cardiac surgery with CPB. In addition, many patients with trisomy 21 have either overt or functional hypothyroidism (up to 30%). In these patients and especially infants, T3 infusion can be very effective at improving myocardial function and decreasing the need for high-dose inotropic support (302,303). Patients with refractory LCOS who are receiving high doses of inotropic support should have thyroid function tests measured with consideration for initiation of T3 (triiodothyronine) infusion, 0.05 to 0.15 $\mu\text{g/kg/h}$.

CPR AND ECPR IN THE PCICU

Cardiac arrest is a constant threat in the PCICU and vigilant monitoring and assessment to identify patients at risk and to address treatable causes before an arrest are important tasks in every CICU. Decreasing peripheral perfusion, increasing acidosis and serum lactate, as well as decreasing somatic NIRS values are all used to assess this risk (304). Despite best efforts, sudden arrest from causes such as paroxysmal arrhythmias or PH crises happen all too frequently in the PCICU. Immediate response, institution of effective chest compressions, assuring oxygenation and ventilation, rapid defibrillation or cardioversion, and administering standard resuscitation drugs such as epinephrine and atropine rapidly and prompt cardioversion or defibrillation are very important. However, in the CICU, there are a number of scenarios where standard resuscitative measures will not be effective. Rapid surgical assistance to reopen the sternum of the arrested patient with cardiac tamponade, for instance, is essential. If patients are not responding rapidly to standard measures, rapid institution of ECMO, known as ECPR, is now the standard approach in many centers. Such a system requires considerable institutional resources to equip and train personnel. Survival rates of ECPR are as high as 30% to 40% in experienced programs. Virtually all of these patients would have died without this therapy (305). (See Chapter 21 for a detailed discussion of mechanical support therapies.)

THE CATHETERIZATION LABORATORY AND THE PCICU

Care of Postcatheterization Patients

With increasingly invasive procedures performed in the catheterization laboratory on progressively smaller and sicker patients, a number of these children will need PCICU admission for observation and treatment of postcatheterization issues. These can include low CO after many procedures such as aortic valve balloon angioplasty in the neonate, pulmonary reperfusion injury or hemorrhage after extensive pulmonary artery angioplasty, PH after procedures such as pulmonary vein angioplasty and stenting, severe catheter-induced arrhythmia, or heart block or cardiac arrest after induction of anesthesia

in a patient with preexisting severe myocardial dysfunction. These patients often do not have the same hemodynamic monitoring catheters, that is, arterial, right and left atrial catheters, as postsurgery patients. Their clinical examination parameters are very important. Clear communication between the cardiac catheterization team and the CICU for high-risk patients, identical to that of patients undergoing cardiac surgery, is essential for optimal care of these patients.

Catheterization of ICU Patients

Many PCICU patients undergo preoperative evaluation or interventions in the catheterization laboratory. Patients with known or suspected residual defects who are not progressing in their ICU course in terms of hemodynamic or respiratory support should have serious consideration for thorough hemodynamic and anatomic assessment in the catheterization laboratory. Echocardiographic data are important, but should not be relied upon exclusively for therapeutic decision making in PCICU patients. Not only can residual defects be assessed in detail with catheterization but also pulmonary vein saturations are often helpful to distinguish pulmonary parenchymal disease from other causes of arterial desaturation. This also affords the opportunity for intervention, where additional surgery would be high risk. This includes patients on ECMO. In addition, patients on mechanical support may require catheter therapy to create a larger atrial communication for left heart decompression or correct positioning of intracardiac support catheters. There should be a relatively low threshold for performing cardiac catheterization in PCICU patients.

MEDICAL CONDITIONS IN THE CVICU

Among the most common medical conditions reported in PCICU admission are myocarditis, cardiomyopathies, acute or chronic transplant rejection or graft dysfunction from coronary arteriopathy, and severe infective endocarditis (306). Common pathophysiology often includes a dilated, poorly functioning left ventricle with acute congestive heart failure. Management principles in the acute PCICU setting are the same as noted above, under Prevention and Management of Low Cardiac Output Syndrome. Chapters 55 and 65 contain detailed discussions of these conditions. Diagnosis and specific treatment for the underlying cause of heart failure is of paramount importance. Patients range from those requiring a short PCICU stay for additional diuresis or low-dose inotropic therapy to those who will go on to require mechanical support. A common issue with myocarditis, cardiomyopathy, or transplant rejection patients is when to initiate some form of mechanical support in a marginal patient with established LCOS. Any reversible or treatable causes are addressed. Patients with continued low CO despite significant inotropic support, with respiratory insufficiency, with risk for or experiencing multiorgan failure or cardiac arrest must be strongly considered for such therapy. Serial echocardiograms, serum lactate, mixed venous oxygen saturation measurements, and serum troponin or B-natriuretic peptide levels can be important modalities to assist in decision making.

THE LOW BIRTH WEIGHT INFANT

LBW infants weighing <2,500 g are increasingly admitted to PCICUs, both after and before palliative or corrective cardiac surgery or cardiac catheterization. The emphasis on early total

correction of two-ventricle lesions and on early palliation of single-ventricle lesions had led to the increase in this population. Although complex surgery with CPB can be accomplished in these patients, problems of the premature infant such as intraventricular hemorrhage or bronchopulmonary dysplasia have important implications for these patients (307). Overall survival is lower than for full term and normal birth weight infants. Bloodstream infections are common and a prominent feature for increased mortality (308,309). This problem may be minimized by the routine preoperatively percutaneous placement of central catheters, which have a very low infection rate (310). Alternative approaches to LBW neonates, such as the hybrid Stage I palliation for HLHS, versus conventional Norwood Stage I palliation, have not improved survival in these infants (311). Prolonged treatment with PGE₁ for ductus-dependent lesions has been described as an alternative to early surgical intervention (312). The LBW population in the PCICU must have multidisciplinary consultation, particularly from neonatologists, to assist in identifying and treating conditions unique to this population.

THE ADULT WITH CONGENITAL HEART DISEASE

The issue of critical care for the adult with CHD is a complex one and the setting of care may be in a PCICU in a children's hospital, a general cardiothoracic surgical ICU in an adult hospital, or a specialized unit for adults with CHD (313). Specialized knowledge and experience in caring for the adult with CHD is important for the intensivist involved with these patients. The multiorgan pathophysiology of long-standing CHD is different from the young child and arrhythmias, myocardial failure, renal dysfunction, coagulation abnormalities, and neurologic dysfunction are common in this population. Expert cardiologists specializing in adult CHD are very important for consultation and coordination of the adult subspecialists needed, including neurologists and nephrologists. Each institution must develop a standardized, coordinated, multidisciplinary approach to these patients.

CONCLUSIONS

Cardiac intensive care in infants and children with congenital and acquired heart disease is a rapidly evolving field with a tremendous amount of new knowledge every year. No matter what the exact setting for the care of these patients, whether in the neonatal intensive care unit, within a PICU or in a dedicated cardiac intensive care unit, the institution must provide the adequate resources and support for this very intensive system of care. Multidisciplinary collaboration is key to maximize outcomes. The melding of state-of-the-art knowledge and techniques in Cardiology, Surgery, Intensive Care, Anesthesia, Nursing, Respiratory Therapy, and Perfusion, continually yields new approaches to address the needs of these complicated patients.

Elizabeth D. Blume ■ Ravi R. Thiagarajan ■ Peter C. Laussen

Mechanical support of the circulation for infants and children has an important role in providing short-term circulatory support during reversible myocardial failure such as during fulminant myocarditis (1,2), as a means of cardiopulmonary support before and after cardiac surgery (3–7), and as a long-term bridge to cardiac transplantation (8–11). Mechanical circulatory support devices (MCSDs) can be divided by duration of support into short-term support and longer-term support. Short-term support (days to weeks) may be provided by cardiopulmonary bypass (CPB), extracorporeal membrane oxygenation (ECMO), intra-aortic balloon pump (IABP) counterpulsation, or centrifugal ventricular assist devices (VADs). Longer-term support (weeks to months) may be accomplished by pulsatile paracorporeal or implantable VADs or axial flow implantable VADs. Table 21.1 summarizes the types of MCSDs available currently for pediatric patients in the United States.

Selection of the optimal mode of circulatory support is a critical issue in pediatric patients and depends to a great extent upon the anatomy and pathophysiology, patient size, and anticipated duration of support. There are currently no established guidelines for the indications and management of cardiac mechanical support, and there is considerable interinstitutional variability with respect to utility and outcomes. In general, institutions with a well-established ECMO service for either respiratory or cardiac failure are more likely to utilize this form of support for the failing circulation, while institutions with close collaboration with adult VAD programs are more likely to use other forms of MSCD in the older, larger patients. In addition, surgeon preference, case mix, surgical techniques, and CPB management are confounding factors that make institutional comparisons difficult. No prospective randomized trials comparing the indications for and modes of mechanical support have been undertaken although considerable information that has been accumulated in national and international registries for ECMO and VAD provides a framework for decision making. While it could be argued that a MSCD program, including at least ECMO, should be readily available in any center undertaking complex congenital cardiac surgery, it is critical to establish a structured and coordinated team.

ANATOMIC AND PHYSIOLOGIC DIFFERENCES IN CHILDREN

The major consideration in the design and development of safe circulatory support systems for children is the need to accommodate a large range of patient sizes, from newborns to young adults. MCSDs that employ a flexible membrane pump, such as the paracorporeal pneumatic devices, rely on a number of pump sizes to cover the range of patient sizes

encountered in pediatric practice. This adds considerably to the cost of development and patient care. Beyond implications for the pump itself, however, size considerations exist for all aspects of device design for children including cannulas and control systems. Furthermore, the diverse anatomic variations encountered in complex congenital heart disease challenge the design of such devices. For example, abnormalities of viscerotrial situs, such as situs inversus and abnormalities of the location of the cardiac apex (dextrocardia), complicate the application of many existing pump designs.

The design of circulatory support devices for children must take into account other unique physiologic issues. The susceptibility to anticoagulation-related complications is particularly notable in infants and children as evidenced by the important risk of intracranial hemorrhage during infant ECMO support (12,13). Newborns are known to manifest an exaggerated systemic inflammatory response (14–18) following CPB and during ECMO support that may induce multisystem organ dysfunction.

Other factors have developmental components as well such as changes in pharmacokinetics of anticoagulant medications. The ideal mechanical circulatory support system for children, therefore, must provide maximal biocompatibility resulting in minimal activation of systemic inflammatory cascades and avoidance of high-dose, multiagent anticoagulation. Children are also vulnerable to infectious complications during mechanical circulatory support, which are a frequent cause of perisupport mortality (19–21). Thus, choosing an implantable system that does not require multiple skin penetrations for drive lines or other device components is an important goal. Since urgent institution of support may be required to treat cardiac arrest after cardiac surgery or acute myocarditis, some device designs must allow for “rapid deployment” (21,22). Finally, the use of MCSDs in children for long-term permanent use as an alternative to heart transplantation, so-called destination therapy, has not been explored. One could imagine this possibility in the future if technologic advances could overcome the issues of growth and development.

SHORT-TERM MODES OF MECHANICAL CIRCULATORY SUPPORT

Cardiopulmonary Bypass

The first mechanical circulatory support systems for children began in the 1950s shortly after the first successful adult heart-lung machine implementation. In 1954, Gibbon (23) repaired an atrial septal defect using the adult circulatory support system, and at the same time, Lillehei's group (24) began using cross-circulation to repair congenital heart lesions in children. Kirklin et al. (25) developed a pump oxygenator that

TABLE 21.1 Types of Mechanical Circulatory Support for Children

Support Name	Type	Clinical Experience and Age Supported
Short-Term Support		
ECMO	Extracorporeal, centrifugal	Extensive pediatric, all ages
Bio-Pump ^{a,b}	Extracorporeal, centrifugal	Extensive pediatric, all ages
Intra-aortic balloon pump	Extracorporeal, counterpulsation	Limited pediatric, older children
Abiomed BVS 5000 ^{a,c}	Extracorporeal, pneumatic	Limited pediatric, older children
Chronic Support		
Thoratec ^{a,d}	Paracorporeal, pneumatic	Limited pediatric, older children
Heartmate V-E ^{a,e}	Implantable, electric	Limited pediatric, older children
Medos HIA-VAD ^f	Paracorporeal, pneumatic	Increasing pediatric, all ages
Berlin Heart EXCOR ^g	Paracorporeal, pneumatic	Increasing pediatric, all ages
DeBakey VAD Child ^{a,h}	Implantable, axial flow	Limited pediatric, 5–12y

^aFDA approved in the United States.^bBio-Pump (Medtronic Bio-Medicus, Minneapolis, MN).^cABIOMED BVS 5000 (ABIOMED, Inc., Danvers, MA).^dThoratec VAD (Thoratec, Corp., Pleasanton, CA).^eHeartMate LVAS (Thoratec, Corp., Pleasanton, CA).^fMEDOS HIA (MEDOS Medizintechnik AG, Stolberg, Germany).^gBerlin Heart EXCOR (Berlin Heart AG, Berlin, Germany).^hDeBakey VAD Child (MicroMed Technology, Inc., Houston, TX).

required much less prime volume than earlier versions. The next major improvements came in the 1970s with the development of deep hypothermic circulatory arrest in infants by Casteñeda (26) and Barratt-Boyes (27), which allowed surface cooling and shorter CPB times. Over the next several decades, incremental improvements in CPB technology and operative techniques contributed to a significant reduction in mortality rates associated with pediatric cardiac surgery. Nonetheless, the potential morbidity following the use of CPB in infants and children continues to be a significant limitation to this mode of mechanical circulatory support.

Although an in-depth discussion of the mechanisms and techniques of CPB is beyond the scope of this chapter, it is worth understanding the overall principles of CPB in order to assess other MCSs, such as ECMO and VADs, and note specific differences to adult CPB. The CPB circuit has a number of components including arterial and venous cannulae, circuit reservoir, pump, oxygenator, and heat exchanger. CPB is an “open” mechanical support system, allowing for blood, air, and particulate matter to be returned to the circuit reservoir via cardiectomy suckers. This is an important distinction to ECMO and VAD circuits, which are both closed systems; any air entering the closed circuit will cause an airlock and these circuits do not have a reservoir volume to compensate for changes in circulating blood volume. Most pediatric systems use a *roller pump* with flow rates governed by the internal diameter of the tubing, the amount of occlusion of the roller, and the revolutions per minute (rpm) of the pump head. Typically, the membrane-type *oxygenator* systems are used, consisting of microporous membrane with hollow fiber or folded membrane, which must function efficiently at a wide variety of pump flow rates. Some considerations for cannulation for CPB are unique to congenital heart surgery. Venous cannulation in neonates and infants may be single or multiple depending on the anatomy and bypass technique. Obstruction

to venous return is more likely due to the small vessel size and will increase venous pressures, thereby decreasing perfusion pressure to the cerebral and splanchnic circulations. In particular, an elevated SVC pressure will reduce cerebral blood flow, increase the risk of cerebral edema, and reduce the rate of cerebral cooling. Systemic-to-pulmonary shunts such as a patent ductus arteriosus and aortopulmonary collateral vessels must be controlled when initiating CPB to prevent excessive pulmonary flow with resultant increased blood return to the heart, myocardial distention, systemic hypoperfusion, and uneven cooling or rewarming.

Body-indexed pump flow rates are generally higher in neonates and infants reflecting a relatively increased metabolic rate in this age group. During bypass, there is no one measure of index that assures adequate perfusion. Generally flow rates of 100 to 150 mL/kg/min, or indexed flows to 2.2 to 2.5 L/min/m², should provide adequate tissue perfusion at normothermia. Venous oxygen saturation of >75% suggests adequate perfusion. However, these values may be misleading in patients with poor venous drainage, severe hemodilution, or malposition of the aortic cannula or in the presence of a large left-to-right shunt. Online continuous monitoring of blood gas and oxygen saturation is important to identify trends in oxygen extraction.

During hypothermia, there are two broad bypass management strategies. The first strategy is deep hypothermia circulatory arrest (DHCA) (<20°C) with low/intermittent flow or circulatory arrest. DHCA provides optimal operating conditions for intracardiac repairs with an empty, relaxed heart and reduces the duration of bypass and exposure of circulating blood to foreign surfaces. Prolonged brain ischemia is a major disadvantage and risk relates to both DHCA time and temperature. Low-flow deep hypothermic bypass is preferable and offers improved neurologic protection. Flow rates between 30 to 50 mL/kg/min are often referred to as “low flow,” but

the optimal flow rates during low-flow bypass are not firmly established.

The second strategy is moderate hypothermia with normal or increased pump flow. Bicaval cannulation is generally used, the risk of cerebral ischemia is reduced, but CPB is prolonged and operative conditions may not be ideal.

It is well recognized that the exposure of blood elements to the nonepithelialized CPB circuit along with ischemic-reperfusion injury induces a systemic inflammatory response (14–18). The effects of the interactions of blood components with the extracorporeal circuit are magnified in children due to the large bypass circuit surface area and priming volume relative to patient blood volume. Humoral responses include activation of complement, kallikrein, eicosanoid, and fibrinolytic cascades. Cellular responses include platelet activation and an inflammatory response with an adhesion molecule cascade stimulating neutrophil activation and release of proteolytic and vasoactive substances (29,30).

The clinical consequences of CPB include increased interstitial fluid, generalized capillary leak, and potential multiorgan dysfunction. Total lung water is increased with an associated decrease in lung compliance and increase in the alveolar to arterial oxygen ($A-aO_2$) gradient. Myocardial edema results in impaired ventricular systolic and diastolic function. A secondary fall in cardiac output by 20% to 30% is common in neonates in the first 6 to 12 hours following surgery, contributing to decreased renal function and oliguria (31). Sternal closure may need to be delayed due to mediastinal edema and associated cardiorespiratory compromise when closure is attempted. Ascites, hepatic congestion, and bowel edema may affect mechanical ventilation, cause a prolonged ileus, and delay feeding. A coagulopathy post-CPB may contribute to delayed hemostasis. Strategies that have evolved thus far to limit the effect of the endothelial injury resulting from the systemic inflammatory response include limiting both the time spent on CPB and use of DHCA, hypothermia, steroids, and aprotinin (a serine protease inhibitor) may also limit activation of the inflammatory response. Attenuating the stress response, the use of antioxidants such as mannitol, altering prime composition to maintain hematocrit and oncotic pressure, and ultrafiltration during rewarming or immediately after bypass are also used to limit the clinical consequences of the inflammatory response (32–34).

Hypothermia and Cerebral Protection

Techniques of deep hypothermia with or without circulatory arrest have extended the safe duration of CPB in children, particularly neonates and infants, enabling improved surgical conditions and patient outcome. As mortality has decreased, an increasing emphasis has been placed on patient morbidity following repair, and in particular, the consequences of deep hypothermia and low perfusion have become closely scrutinized.

The brain is particularly sensitive to ischemia; therefore, MSCD carries risk for cerebral ischemic injury. Hypothermia is the principle method used for cerebral protection during CPB, effecting both pressure-flow and metabolism-flow cerebral autoregulation (35–37). A reduction in oxygen consumption and metabolic rate during deep hypothermia explains in part the increase in tolerance to cerebral ischemia produced by hypothermia. Other factors possibly contributing to the protective effects of hypothermia include altered cellular metabolism with an increase in high-energy phosphates and intracellular pH, reduced neurotransmitter release, and that the neonatal and infant brain may be more tolerant of cerebral ischemia than the adult brain.

However, diffuse cerebral abnormalities can occur in patients after open heart surgery in children and adults, including global

and watershed injuries related to hypoperfusion or hypoxemia, and multifocal lesions presumed secondary to embolic events (38–40). The early clinical manifestations of neurologic injury in children include seizures, stroke, choreoathetosis (41), and coma. Subtle long-term behavioral, developmental, and motor abnormalities have now been associated with neurologic injury during hypothermic CPB, regardless of strategy, and support the importance of early developmental intervention. The Boston Circulatory Arrest Study (42) demonstrated a strong association between the duration of circulatory arrest and the occurrence of postoperative seizures that become more likely after circulatory arrest duration of 40 minutes. Analysis of developmental outcome at 1 year of age in these patients indicated a significant association between the occurrence of postoperative seizures and a worse than normal outcome for psychomotor development (43). The risk of neurologic abnormalities increased with the duration of circulatory arrest. Data at 4- and 8-year follow-up in these patients indicate a spectrum of both motor and language delays and abnormalities that also correlate with the incidence of postoperative seizures (44,45). Recently, genetic polymorphisms have been recognized that may predispose to impairments in neuronal repair ability (46).

While hypothermia is the principle method for providing protection during CPB, the means by which hypothermia is induced and maintained is critical. Because of the large body surface area (BSA) to mass ratio in neonates and infants, a 2- to 3-degree reduction in core temperature is common prior to bypass. Respiratory alkalosis secondary to mechanical ventilation reduces cerebral blood flow and should be avoided. Cannula position is important as noted above; obstruction to systemic venous return by venous cannula decreases cerebral perfusion pressure, and an obstructive or malpositioned aortic cannula will also decrease cerebral blood flow and effective cooling. Shunts and collateral vessels must be controlled when initiating bypass to prevent excessive runoff to the lungs and return to the heart, resulting in myocardial distention, systemic hypoperfusion, and uneven cooling or rewarming. Once on bypass, rapid cooling should be avoided as this results in uneven cooling of the brain; cooling times of 20 to 25 minutes have been advocated for infants and neonates requiring CPB and DHCA. Possible pharmacologic manipulations include using vasodilation drugs to facilitate cooling and rewarming and steroids are commonly administered to stabilize membranes in an attempt to reduce cerebral edema.

The use of crystalloid pump primes may be associated with an increase in total body water after hypothermic CPB in neonates and infants, secondary to a reduction in plasma oncotic pressure. This will contribute to postoperative capillary leak and can potentially delay recovery. Variability in the target hematocrit during hypothermic CPB remains between centers, but maintaining a hematocrit around 30% appears to be optimal with respect to altered blood viscosity during hypothermia and the maintenance of oncotic pressure and oxygen-carrying capacity (47).

The blood gas strategy during hypothermic CPB is also an important consideration (40,48). Carbon dioxide (CO_2) is a potent cerebral vasodilator in both awake and anesthetized patients with or without CPB. During CPB and hypothermia, cerebral blood flow continues to increase with $PaCO_2$; however, this response is attenuated in neonates and infants with deep hypothermia and reflects cold-induced vasoparesis. During hypothermia, the solubility of CO_2 increases and the neutral pH of both water and blood are reset in the alkaline direction. In the alpha-stat strategy, no compensation is made for the alkaline shift. The alpha-stat strategy theoretically maintains a more normal intracellular pH and therefore electrochemical neutrality with preserved enzymatic function. Further, the uncoupling of flow metabolism is less pronounced, thereby limiting luxuriant cerebral flow during CPB.

Figure 21.1. Extracorporeal membrane oxygenator circuit with membrane gas exchange device and roller pump.

However, in the context of low mean perfusion pressure, flow, and temperature, cerebral perfusion may be inadequate to meet metabolic demands and cerebral cooling may be nonhomogeneous. In contrast, the pH strategy aims to maintain a normal pH over varying temperatures, and CO₂ must be added to the oxygenator gas mixture during deep hypothermia. The increased cerebral blood flow associated with pH-stat regulation may result in an increase in air or particulate emboli to the brain. Clearly, this is a concern in congenital heart disease with the presence of intra- and extracardiac communications and the need for intracardiac surgical repairs. In addition, pH-stat strategies increase cerebral blood volume, which may result in hyperemia and edema particularly during reperfusion. However, luxuriant cerebral flow and perfusion have the advantage of enhancing global cerebral cooling and reducing cerebral steal from aortopulmonary shunts. Hypothermia causes a left shift of the oxyhemoglobin curve and is further shifted to the left by an alkaline pH. Off-loading of oxygen in the tissues is impaired and the left shift is counteracted by more acidotic pH such as provided by the pH strategy.

Many years of research and understanding of the effects of CPB on the pediatric patient have created a wealth of information that can be extrapolated to the management strategies of other MCSDs, such as ECMO and VAD. Cerebral protection, biocompatibility, and coagulation monitoring continue to be long-term areas of research common to all MCSDs.

Extracorporeal Membrane Oxygenation

ECMO was first introduced as a form of respiratory support in children with severe lung disease and is the most common approach to pediatric mechanical cardiac support today. In venoarterial ECMO (VA ECMO), blood is drained from the venous circulation into the ECMO circuit, pumped into the oxygenator for gas exchange, and returned to the arterial circulation as shown in Figure 21.1. Thus, VA ECMO provides both cardiac and respiratory support and is the most commonly used form of ECMO to support children with cardiac dysfunction (1). In venovenous ECMO (VV ECMO), deoxygenated blood drained from the venous circulation is oxygenated and returned back to the venous circulation and circulation is maintained by native cardiac function. Thus, VV ECMO is commonly used to support those with pure respiratory failure, as it does not provide mechanical circulatory support. The Extracorporeal Life Support Organization (ELSO) collects

data from neonates, children, and adults supported with ECMO for all indications from 140 centers worldwide and has provided important knowledge on outcomes following ECMO that has served as an invaluable guide to the clinical use of ECMO (49).

Indications for ECMO use have evolved over time. Its use in providing biventricular support and oxygenation in pediatric patients with a failing circulation has increased. Reduction in the need for ECMO as respiratory support, particularly in neonates, has occurred as a result of newer therapies such as inhaled nitric oxide, high-frequency oscillatory ventilation, surfactant therapy, and permissive hypercapnia (49–52). As a result, the current patients requiring ECMO for respiratory support are sicker and have usually failed many medical therapies. Consequently, their survival has declined over recent years. Cumulative data reported by the ELSO (49) from 140 centers through to January 2010 provide an important insight into the outcomes and changing landscape of ECMO. In the 2010 report, 75% of all neonates placed on ECMO for respiratory support survived to hospital discharge. The outcome for older patients placed on ECMO for respiratory support is lower than that for children. The reported cumulative survival for pediatric is 56% and for adult patients is 52%. Table 21.2 outlines the survival in the respiratory group by diagnostic category.

TABLE 21.2

Survival Following ECMO Cannulation in Neonates by Respiratory Diagnostic Group Compared with Cardiac Neonates

Diagnosis	Survived (%)
Meconium aspiration syndrome	94
Primary pulmonary hypertension of newborn	78
Sepsis	75
Air leak syndrome	74
Congenital diaphragmatic hernia	51
Cardiac disease	39

Adapted from Salvin JW, Laussen PC, Thiagarajan RR. Extracorporeal membrane oxygenation for postcardiotomy mechanical cardiovascular support in children with congenital heart disease. *Paediatr Anaesth* 2008;18(12):1157–1162.

In contrast to respiratory ECMO, the use of ECMO for the treatment of circulatory failure following congenital cardiac surgery (Table 21.3) or as a bridge to cardiac transplantation has increased over the past decade (6–11,53–67). However, despite the increased enthusiasm for cardiac ECMO, the survival to hospital discharge as reported by ELSO (49) (39% for neonates and 47% for pediatric patients) has not increased and remains lower than the survival outcomes reported following respiratory ECMO (Fig. 21.2). The average duration for cardiac ECMO runs reported to ELSO over the past 15 years has increased slightly from approximately 4 to 5 days to 5 to 8 days, and the longest reported run has been 93 days (49). These data highlight the fact that ECMO should be viewed as a short-term circulatory support device.

There are significant differences between ECMO for circulatory support compared to respiratory support. Many cardiac ECMO patients are postcardiotomy patients following surgery for congenital heart surgery. A small number of these patients are placed on ECMO after failing to wean from CPB after congenital heart surgery (55). In these cases, severity of organ dysfunction and illness prior to ECMO deployment,

residual hemodynamic lesions, underlying pathophysiology, and end-organ dysfunction prior to ECMO support play an important role in survival following ECMO support. Thus, timing of initiation of ECMO support is important to achieve successful outcomes (57). ECMO facilitates ventricular recovery by reducing myocardial wall tension, increasing coronary perfusion pressure, and providing adequate systemic perfusion with oxygenated blood (60,61,65). In infants, where myocardial failure can be either uni- or biventricular and associated with respiratory insufficiency or pulmonary hypertension, ECMO is the preferred means of mechanical support. In contrast to the concept of “resting the lungs” for patients who are placed on ECMO for respiratory failure and lung injury, it is important that the heart regain contractile function and conduction in order to prevent involution of the myocardial mass. This will require evaluation with echocardiography to prevent overdistension of the heart. As noted above, the ECMO circuit is a “closed” circuit with limited ability to handle any air in the venous limb of the ECMO circuit, and careful de-airing of the venous cannula during initiation is essential.

Figure 21.2. Cardiac ECMO volume and survival outcomes. The use of cardiac ECMO has increased dramatically over time, although survival rates continue to remain stable. (Data from the ELSO International Summary 2010.)

TABLE

21.4

Indications for Mechanical Circulatory Support in Infants and Children

- Preoperative resuscitation
- Inability to wean from CPB
- Postcardiotomy
- Following in-hospital cardiac arrest
- Low output cardiogenic shock
- Myocarditis
- Cardiomyopathy
- Refractory arrhythmia
- Bridge to transplantation

Indications for Cardiac ECMO

Indications for cardiac ECMO are similar to indications for all MCSDs (Table 21.4). It can be an effective bridge to recovery, to transplantation, or to longer term mechanical support.

I. Preoperative Resuscitation and Stabilization:

ECMO may be beneficial for critically ill patients with congenital heart disease prior to cardiac surgery (53,58), enabling resuscitation, optimization, and prevention of end-organ dysfunction. Indications include severe low cardiac output states from left-sided obstructive lesions (e.g., critical aortic stenosis), pulmonary hypertension (e.g., obstructed total anomalous pulmonary venous drainage), or severe hypoxemia (e.g., transposition of the great arteries).

II. Inability to Wean from CPB

There is limited utility for ECMO as a bridge to recovery of ventricular function, and overall survival is poor when patients are placed on ECMO because they cannot be weaned from CPB in the operating room (54–57). Unrecognized residual or irreparable defects are major factors determining successful outcome in this circumstance, and careful assessment in the operating room with a combination with echocardiography and the measurement of oxygen saturations and intracardiac pressures may help identify correctable anatomic defects. Early transport to the cardiac catheterization laboratory may be necessary to diagnose residual defects (67). A major complication in this group transitioned directly to ECMO from CPB is the risk for hemorrhage. A lower activated clotting time (ACT) is used in this circumstance often needing small increments of protamine (1 mg/kg) until a target ACT of 160 to 180 seconds is achieved. Infusions of antifibrinolytic drugs such as aprotinin (bolus 30,000 IU/kg, infusion 10,000 IU/kg/h), tranexamic acid (bolus 100 mg/kg, infusion 10 mg/kg/h), or epsilon aminocaproic acid (bolus 100 mg/kg, infusion 30 mg/kg/h) should also be considered. Exploration of the chest is usually necessary, particularly if the bleeding persists at >10 to 15 mL/kg/h or problems with ECMO flow are encountered from tamponade-like effect.

Ideally, only children with potentially reversible myocardial injury who cannot be weaned from CBP should be considered candidates for ECMO, although this may be extremely difficult to determine in the operating room immediately following cardiac surgery. Considerations include preoperative condition, intraoperative course, and likelihood of becoming a suitable transplant candidate. When a patient is placed on ECMO in the operating

TABLE

21.5

ECMO Survival of Congenital Heart Disease in Infants and Children after Corrective Surgery

Procedure	Total Reported	Survived (%)
Anomalous Venous Return repair (age < 30 d)	286	48
	134	51
Common atrioventricular canal repair	66	41
BDG operation	95	31
Fontan Operation	876	30
Stage 1 palliation (Norwood; age < 30 d)		

Data from Extracorporeal Life Support Organization, International Summary 2010.

room, it is important for discussions with the patient's family to be clear and direct. Recovery of myocardial function should be expected within 2 to 3 days (56,57). If this is not evident, proceeding to transplant evaluation or withdrawal from support must be considered.

III. Postcardiotomy

ECMO is an effective therapeutic option for infants and children who have had a period of relative stability after successful termination of CPB, for whom significant residual cardiac defects are excluded (Table 21.5) (49). Because patients were stable enough to wean off CPB, bleeding is less of an issue. For this group, cannulation can be undertaken through the chest at the bedside; however, if sufficiently stable, neck or femoral sites are preferable. Myocardial or respiratory failure causing a low cardiac output state, hypoxemia or pulmonary hypertension, and cardiac arrest are the major indications in this group, and survival rates as high as 60% to 70% have been reported provided ECMO is instituted rapidly and effectively (49,54–62). Survival for patients with single ventricle lesions supported following surgery (Norwood, Bidirectional Glenn [BDG] or Fontan operations) is lower than those with biventricular circulations requiring ECMO support (59–63).

IV. In-Hospital Cardiac Arrest and Cardiopulmonary Resuscitation (ECPR)

Survival and outcome of in-hospital resuscitation in pediatric patients following a cardiac arrest is extremely poor. Even within a highly monitored environment such as a pediatric intensive care unit, the survival following cardiac arrest has only been reported to be between 9% and 31% (68,71). The duration of cardiac arrest and quality of resuscitation are important determinants of outcome and reports have noted that a critical threshold is 15 minutes for return of circulation for survival to hospital discharge (68). There are a number of reports showing that ECMO can be successfully deployed in children receiving active resuscitation and chest compressions (5,6,22,23,64,69,70), and that the use of ECMO to support failed CPR (ECPR) in some patients can promote survival. Since ECMO deployed during CPR should be conducted expeditiously and avoid significant delays, a "rapid response" ECMO system has been established at some institutions to initiate ECMO during active resuscitation efforts (22,23,70). As a guideline, ECMO should be considered in patients who have suffered a witnessed cardiac arrest and received rapid institution of effective and monitored CPR,

have no or inadequate recovery of cardiac function within 5 to 10 minutes of initiating resuscitation, and have no obvious contraindications for ECMO.

The aim of a rapid-response system is to provide systemic perfusion and oxygen delivery as soon as possible to prevent end-organ injury. Ideally, this should be within 30 minutes of starting resuscitation, although it may take longer if cannulation is complicated. Postcardiotomy cannulation of the atrium is best achieved via a reopened sternotomy, which is usually the access mode of choice. In other patients, experienced practitioners can rapidly gain access via the neck vessels. Groin vessel cannulation has been reported, even in the infant (71). It is important to provide effective and monitored resuscitation during cannulation, and there will be times during cannulation that chest compressions will need to be briefly discontinued. Mild hypothermia should be induced during resuscitation, and should be continued once ECMO has been started to possibly provide end-organ and specifically neurologic protection. Because the aim is to provide systemic perfusion as soon as possible with ECMO flow, there is usually insufficient time to blood prime the ECMO circuit. This means that infants and small children are extremely hemodiluted when ECMO flows are started, but once flow is established, blood products can be added or the priming crystalloid can be removed via hemofiltration.

Determining the relative contraindications to ECMO support during active resuscitation attempts can be difficult. Patients with repaired two-ventricle defects who have a sudden or unexpected event leading to cardiac arrest are good candidates for early initiation of ECMO during resuscitation because effective CPR is more likely to maintain perfusion and oxygen delivery during chest compressions, thereby decreasing the risk for end-organ injury (10,11). In contrast, patients with cavopulmonary connections, that is, Fontan or BDG anastomosis, have been difficult to resuscitate using ECMO for several reasons (59–63). These patients may have occluded or abnormal venous and arterial access, thereby limiting possible cannulation sites. An inability to maintain adequate systemic oxygen delivery during CPR and cerebral venous hypertension during CPR with chest compressions may hinder neurologic outcome. Another complicated group includes patients with pulmonary hypertension and those with systemic outflow obstruction. These patients, similar to the cavopulmonary connection group, are at significant risk for inadequate oxygen delivery during CPR, contributing to subsequent end-organ injury.

V. *Cardiomyopathy, Myocarditis, and Bridge to Cardiac Transplantation*

Patients who present with acute fulminant myocarditis can be successfully managed with ECMO with excellent outcomes (10,11,72–74). They may present with full cardiac arrest, shock from an extreme low cardiac output state, or hemodynamically unstable dysrhythmias including ventricular tachycardia or heart block. The heart is usually distended and contracting very poorly. Prompt institution of ECMO may allow sufficient resuscitation and stabilization to prevent end-organ injury and enable the myocardium to rest while awaiting potential recovery. After instituting ECMO, it is essential that the heart be fully decompressed, and urgent left atrial vent placement may be necessary (67). The heart may not begin to eject for the first 24 to 36 hours after initiating ECMO, although recovery of electrical activity within the first few hours should be expected. If recovery of ventricular ejection is not evident within 2 to 3 days, ECMO can be continued either as a bridge to transplantation or as a bridge to alternative longer-term support with a VAD, if feasible. Transplant-free survival for patients with

acute fulminant myocarditis requiring ECMO support is reported to be >60%.

ECMO should be viewed as a short-term bridge to cardiac transplantation because of the limited donor availability and the time-related risks for complications, such as infection, bleeding, end-organ impairment, problems secondary to immobilization, and difficulties in maintaining adequate nutrition. In our experience at Children's Hospital, Boston, the median time spent on ECMO awaiting heart transplantation has been 140 hours (range 26 to 556 hours), but only 50% of listed patients have been effectively bridged. Our current practice for patient resuscitated with ECMO includes transition to a longer-term MCS to bridge to transplant. The optimal timing for transitioning ECMO patients initially supported with ECMO as a bridge to transplantation to MCSs is unknown but should be considered within 72 to 96 hours if recovery has not occurred prior to the onset of ECMO complications.

ECMO has also been used to effectively support the failing heart after transplantation. This may be necessary immediately after transplantation because of primary graft failure, often in the setting of pulmonary hypertension and acute right ventricular failure of the donor allograft. ECMO is also effective in supporting the transplanted heart during periods of acute rejection (75). The inflammation and myocardial edema are similar to that seen with fulminant myocarditis and lead to a similar spectrum of clinical features. ECMO allows the transplanted heart to decompress with decreased wall tension while antirejection therapy is increased. In our experience, survival to discharge for this indication is 64%, and the median duration of ECMO support has been 4 days.

VI. *ECMO Support during Procedures*

As the complexity and interventions during cardiac catheterization in patients with complex congenital heart disease have continued to expand, patients may be at increased risk for sudden unexpected adverse events. These may range from complications associated with specific intervention to dysrhythmias and low cardiac output state related to wires and catheters within the heart. ECMO support during resuscitation from an acute event during catheterization is beneficial but there are important technical and resuscitative considerations (3,22,76).

Percutaneous cannulation for ECMO can be rapidly achieved using existing catheter access, but staff must be familiar with the technique for upsizing from the catheter sheath to a large-bore ECMO cannula. The catheterization laboratory environment is challenging and resuscitation to ECMO must be well organized to be effective. Often there are conflicting or simultaneous considerations during resuscitation including ongoing chest compressions, cannulation of ECMO, and ongoing efforts by the cath team to stabilize complications such as balloon occlusion of a ruptured vessel.

It is possible to anticipate hemodynamic instability during catheterization in some patients, particularly arrhythmia induction during electrophysiologic studies and radiofrequency ablation (77). The cannulation and support of the circulation using ECMO will enable safe and successful completion of the procedure.

Technical Considerations of ECMO

Children with complex structural cardiac defects may have associated abnormalities with systemic venous damage (e.g., heterotaxy syndromes) or have undergone previous cardiac catheterization or catheter placement that may have caused occlusion of femoral vessels. It is essential, therefore, that the venous and arterial anatomy be well known, including the patency of individual vessels, and be well documented to prevent

inappropriate cannulation attempts. Arteriovenous cannulation is usually employed for cardiac ECMO (78–81), although venovenous bypass can be used in patients who require ventilatory support only. Venous cannulation and ECMO flow via the jugular vein using a double lumen catheter can also provide hemodynamic support in select neonates who have a ductus-dependent circulation, such as hypoplastic left heart syndrome.

The daily management of a patient on ECMO requires attention to cardiorespiratory function, end-organ perfusion and injury, evolving complications such as bleeding or sepsis, and the mechanics of the ECMO circuit (48). Assessing the adequacy of flow and systemic perfusion after initiation of ECMO is essential and well-defined patient and ECMO circuit management protocols must be in place. ECMO flow rates in infants and small children typically range from 100 to 150 mL/kg/min during full circulatory support. Inadequate flow states and/or significant persistent hypotension despite adequate circuit flow may be due to ECMO-related problems with cannula size and position and venous drainage or patient-related factors such as vasodilation and low systemic vascular resistance secondary to sepsis. Venous cannula malposition or inadequate size will limit venous drainage and should be addressed with repositioning or upsizing of existing cannulae, or the addition of a second venous drain. Elevated postmembrane pressures (i.e., >250 mm Hg) may reflect malposition of the arterial cannula or a cannula that is too small and needs to be replaced. Elevated premembrane pressures (i.e., >350 mm Hg) at normal flows without change in postmembrane pressure or evidence of blood-to-gas leak imply membrane oxygenator dysfunction and may need oxygenator replacement. Extensive thrombus evident within the circuit or development of a consumptive coagulopathy with hypofibrinogenemia and thrombocytopenia are indications for circuit replacement. Blood products are administered to keep the hematocrit between 35% and 45% and the platelet count >100,000/mm³. Considerations for cannulation and flow rates once on ECMO may be specific to the underlying cardiac defect or surgical repair. For example, the management of an aortopulmonary shunt in patients with single ventricle physiology may require circuit flows up to 200 mL/kg/min or more to maintain adequate systemic perfusion while accounting for run-off into the pulmonary circulation.

Echocardiography, especially transesophageal imaging, and occasionally cardiac catheterization (67) are used to assess cardiac anatomy and function and to detect residual lesions. In addition, assessment of left atrial hypertension by clinical findings, chest radiograph, and echocardiography is critical. Venting the left atrium may be necessary to lower the left atrial pressure and decrease left ventricular wall stress, thereby minimizing ongoing myocardial injury. Placement of a left atrial vent can be accomplished by direct placement through an open chest or by a transcatheter approach (67). If a patient fails to wean from ECMO or there is delay in anticipated recovery of myocardial function, the possibility of a residual surgical problem must always be considered. This is usually difficult to diagnose by echocardiography alone, and cardiac catheterization (i.e., diagnostic or interventional) should be considered. Safe and successful management of ECMO patients requires a collaborative multidisciplinary team of physicians, surgeons, nurses, and ECMO specialists trained in the management of ECMO patients.

OTHER SHORT-TERM MCS

ECMO has been the mainstay of mechanical circulatory support in infants and children and has been effective in providing circulatory support in the acute setting, especially when

lung disease is also present. However, ECMO has limitations as an effective bridge to transplantation and precludes chronic ambulatory use. In patients unable to be weaned from ECMO who are listed for transplant, transition to a chronic device can be done successfully.

Centrifugal Assist Pump

The centrifugal assist device (BioPump, Medtronic Bio-Medicus, Minneapolis, MN) has historically been the principle means for providing support of the circulation without an oxygenator membrane. This centrifugal pump provides flow by power applied to a rotating magnet coupled to an opposing magnet on a cone-shaped impeller. There are no valves and no obligatory volume displacement by the pump that results in nonpulsatile flow that is both preload and afterload sensitive with priming volumes of 100 mL or less (10,81–85). The various sizes of cone heads available enable this device to be used from infants through to adult sized patients.

Reports using the BioPump predominately as a left ventricular support have demonstrated survival rates of 40% to 70% (10,81–85) when used as a bridge to recovery. Ungerleider (86) reported survival to discharge in an elective strategy following Norwood procedure, with “easier” ICU course. Central nervous system complications, both short and long term, tend to be less prevalent compared to concurrent patients supported with ECMO (82–87). The absence of an oxygenator and reduced lengths of tubing remove an important substrate for cerebral embolic events while the generally reduced level of anticoagulation employed during VAD support may decrease the incidence of hemorrhage. The centrifugal pump VAD enables only short-term support as a bridge to recovery or transplantation. Complications related to this nonpulsatile extracorporeal circuit are similar to those encountered with longer term ECMO use, and patients are unable to ambulate. This is an important consideration, when longer term support allows recovery of end-organ function, improved nutrition, and ability for rehabilitation and ambulation prior to transplantation.

Intra-Aortic Balloon Counter Pulsation

IABP is used for the treatment of left ventricular failure in adults, especially in the postoperative period. Unfortunately, when used in infants and children, results have been disappointing with survival rates <50% (88–93). Many factors contribute to the reduced efficacy of IABP in children. Heart failure in pediatric patients is often due to either right ventricular or biventricular dysfunction, situations where the IABP is less effective. Placement of an IABP in the pulmonary artery has been reported, but is usually problematic, in part because of the small balloon size required and the increased compliance of the pulmonary artery (90). Effective timing of inflation and deflation is more difficult in children because of their relatively rapid heart rates and the variable delay between aortic valve closure and the appearance of the arterial tracing. At heart rates over 160 bpm, the IABP is often reduced to a 1:2 or even 1:4 pumping frequency in order to facilitate cycle timing, at the same time decreasing its effectiveness to 50% to 80% (89–91). The aorta is typically more distensible in infants and in children; therefore, both coronary flow augmentation during diastole (balloon inflation) and afterload reduction during systole (balloon deflation) are likely to be decreased. In addition, the effect of diastolic augmentation of flow to normal coronary arteries, as seen in most pediatric patients, is limited. Severe cyanotic heart disease in children can be accompanied by extensive aortopulmonary collateral vessels, which permit shunting of blood into the pulmonary circulation during balloon inflation, thus reducing augmentation of coronary blood flow.

The smallest balloon system available for children is 2.5 mL, which can be used for neonates as small as 2 kg (92). In general, for children weighing <30 kg, a balloon volume of 0.5 mL/kg is recommended. For balloon inflation, helium is preferred over CO₂, allowing a faster pneumatic response due to its low density. The incidence of vascular complications, such as bleeding, emboli, or limb ischemia, is similar to the adult population where it is reported to be about 10% to 20%. Other potential complications are infection, renal dysfunction, mesenteric occlusion or embolism, and cerebrovascular accidents.

IABP may have a role in the temporary support of the adolescents and adults with single ventricle physiology and poor systolic function during procedures or as a short-term bridge (93). Numerous technical improvements have been made recently to enhance efficacy in the pediatric population. These include modified pumping consoles and small-sized catheters, improved tracking at higher heart rates, more rapid inflation and deflation, and the use of echocardiography for cycle timing. Further studies will be necessary to evaluate the utility of IABP support compared to other techniques for pediatric patients.

LONG-TERM MECHANICAL CIRCULATORY SUPPORT FOR CHILDREN

The use of long-term mechanical circulatory support in children has increased over the past decade as waiting time for pediatric cardiac allografts has increased and understanding of recovery of cardiac function has improved. In adults on chronic term devices, normalization of cardiac output provided by chronic and implantable VADs allows a period of improvement in end-organ function which, combined with patient ambulation and cardiac rehabilitation, optimize patient condition prior to transplant. The use of adult devices in larger children and adolescents has proved successful. In addition, technologic advances have allowed the possibility of mechanical support as a bridge to transplant or recovery for longer periods of time.

The experience with VAD support in infants and children is increasing (94–125); however, it remains challenging due to heterogeneous anatomy and size, anticoagulation strategies, and technical limitations. An important component of these benefits is the ability of the device to allow ambulation and rehabilitation, which cannot be accomplished currently with ECMO and centrifugal VADs. As with ECMO, the selection of appropriate candidates is crucial and surgical problems or residual defects

should be excluded where possible. While ECMO can be instituted by peripheral cannulation of neck or femoral vessels, VADs require direct cannulation of the heart through a sternotomy. Another advantage of VADs is superior ventricular unloading, a prerequisite for myocardial rest and potential recovery.

Clinical Criteria for VAD Placement

VADs can successfully support the circulation and bridge patients to cardiac transplant by improving the patient's cardiac output and oxygen delivery. Therefore, the primary use for VAD is in patients who have unacceptable symptoms or signs of low cardiac output state. In addition to improved oxygen delivery, pulmonary capillary wedge pressure and pulmonary vascular resistance decrease, congestive heart failure symptoms diminish, and nutrition and physical rehabilitation markedly improve in many cases. Thus, VADs have the potential to improve the pretransplant status and to reverse evidence of end-organ dysfunction. Persistent end-organ dysfunction despite maximal medical interventions is the primary indication for VAD in transplant-eligible or listed-patients. These include the obvious symptoms of persistent congestive heart failure and biochemical evidence for renal and hepatic dysfunction. In an attempt to understand the risk factors associated with wait list mortality, Almond et al. (102) analyzed the UNOS database and found that more than 500 children (20% of 1A pediatric candidates) die on the wait list with most being <20 kg (Fig. 21.3A). Risk factor analysis confirmed that wait list mortality was significantly higher for patients who "failed" medical management requiring ECMO or ventilator support (Fig. 21.3B). Subtle symptoms of heart failure such as abdominal pain, vomiting, and anorexia will lead to poor nutrition and should be monitored closely, although no data currently suggest early initiation of VAD support in this population. Early use of VAD, as seen in the current era, with adults (103) in these circumstances may be warranted, although further studies are necessary to understand the true indications for VAD support.

Patients with structurally normal hearts who develop heart failure from acquired heart disease such as myocarditis or who have idiopathic cardiomyopathy are successfully supported and bridged to transplantation with VADs. Compared to patients with structurally normal hearts, the use of chronic MSCD in children with congenital heart disease has not been as favorable with only approximately 30% being successfully bridged to transplant in the congenital group in one study

Figure 21.3. A: Almond et al. analyzed the UNOS registry and found that more than 500 children die on the wait list per year (102). B: Risk factor analysis showed that this mortality was significantly higher in children on MCSDs.

Figure 21.4. Congenital heart disease outcomes are poor. Survival following VAD implantation in pediatric patients with congenital heart disease is significantly worse than in children implanted with structurally normal hearts. (Reproduced from Blume ED, Naftel DC, Bastardi HJ, et al.; for the Pediatric Heart Transplant Study Investigators. Outcomes of children bridged to heart transplantation with ventricular assist devices: a multi-institutional study. *Circulation* 2006;113:2313–2319, with permission.)

(Fig. 21.4). Reoperative status, complex anatomy, nutritional issues, and chronic nature of the diseases are all contributing factors.

In contrast to the ECMO experience, the outcome for children placed on VADs has improved over recent years. Smaller single center studies (106–112) and device registry data (105,113) report approximately a 60% to 70% successful bridge to transplantation in pediatric patients supported with VAD. Improved outcomes in the most recent era (105,111,113) may be related to an increasing experience with the surgical techniques and perioperative care, better patient selection, and earlier introduction of support before irreversible end-organ injury develops, and the application and development of device technology over time.

Adverse Events Related to VAD Support

The adverse event profile and hazard function for death in children are shown in Table 21.6 and Figure 21.5, and are similar

TABLE 21.6		Adverse Events in Pediatric Patients (1993–2003, N = 99) Supported by Short-Term Devices versus Pediatric Patients Implanted with Long-Term Pulsatile Device		
		Chronic	Short Term	p
Adverse Events				
Stroke		9 (13%)	9 (35%)	0.02
Infection		29 (41%)	2 (12%)	0.004
Reoperative bleeding		22 (31%)	11 (42%)	0.32
Hemolysis		13 (19%)	2 (1%)	0.17
Thrombus		8 (11%)	4 (15%)	0.64

Figure 21.5. Overall survival following VAD implant. Of the 99 pediatric patients implanted with VAD, percent survival to transplant is seen. In addition, hazard curve shows highest risk of death in the first 2 weeks following implantation. (Reproduced from Stein ML, Robbins R, Sabati AA, et al. Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS)-defined morbidity and mortality associated with pediatric ventricular assist device support at a single US center: the Stanford experience. *Circ Heart Fail* 2010;3:682–688, with permission.)

to those reported from the larger MCSDB database of adult outcomes (99). Adverse events or complications are a major source of morbidity with chronic pediatric VAD support. Prevention requires meticulous attention to detail with the major morbidity related to problems with chronic anticoagulation (114), neurologic complications, and infection (Table 21.6). Neurologic complications in that series (105) include a 20% incidence of stroke, often fatal or leading to withdrawal of support. This rate of stroke was statistically different between short-term devices (35%) and those intended for long-term support (13%, $p = 0.02$). In a single center report (108) of 25 pediatric patients using predetermined Interagency definitions retrospectively, Stein et al. showed a significant number of morbidities following pediatric VAD implant, including 48% neurologic events. Respiratory failure, infection, renal dysfunction, and bleeding were also common and associated with increased mortality.

Protocols for anticoagulation management vary between devices and centers and include a combination of heparin, coumadin, and antiplatelet drugs. Close monitoring of heparin levels, coagulation profiles, and platelet function is critical. In addition, pediatric research efforts must address biocompatibility issues to mitigate the risks arising from blood-prosthetic surface interactions in these devices, which may be unique to children in whom the lower flow rates are necessary. In addition, long-term follow-up of neurocognitive and quality of life issues in these complex patients must be evaluated, monitored, and compared with appropriate peer groups, in order to evaluate the long-term outcomes and utility of VAD successes.

Use of “Adult” VAD Systems in Children

As noted previously and in Figure 21.3, the use of VADs in children has continued to expand. The currently available devices for children and adolescents in the United States are shown in Table 21.1. The Pediatric Heart Transplant Study Group reported the experience from 24 pediatric heart transplant institutions over the decade of 1993 to 2003, in which 99 pediatric patients received VAD support as a bridge to transplantation (105). In this study, which

Figure 21.6. Era effect of outcome following pediatric VAD implantation. Competing outcomes analysis shows the early mortality improving over time comparing the 1993–1999 (left) era with the current 2000–2003 era (right). (Reproduced from Blume ED, Naftel DC, Bastardi HJ, et al.; for the Pediatric Heart Transplant Study Investigators. Outcomes of children bridged to heart transplantation with ventricular assist devices: a multi-institutional study. *Circulation* 2006;113:2313–2319, with permission.)

included 2,375 pediatric patients listed for transplant, the percentage of patients transplanted with VAD technology implanted increased from 3.2% of all transplants between 1993 and 1999 to 6.6% of all transplants between 2000 and 2003 (Fig. 21.6). This increase in pediatric patients with VAD implantations is most likely multifactorial, including center experience, regulatory issues, and development of smaller technology. Of the 99 patients retrospectively reviewed with a median age of 13.3 years (range 2 days to 17.9 years), 78% had cardiomyopathy (22 patients had congenital heart disease). They were supported for a mean time of implantation of 70 days (range 1 to 465 days). Status prior to implantation included 34 inotrope dependent, 41 requiring ventilatory support, 26 on another form of mechanical circulatory support including 10 on ECMO, 11 on IABP, and 3 on CPB. Of those 70 children who were supported on an adult pulsatile device, 60 (86%) were successfully bridged to transplant. In comparison of this VAD group with over 1,200 patients listed as Status 1, on inotropic support without mechanical support, outcomes both while awaiting transplant and posttransplant were not statistically different. The 5-year survival following transplant for patients on VAD support at time of transplant is comparable to those not requiring a VAD (77% vs. 73%, $p = 0.8$).

Several adult devices have been used in larger children with continued success. Hill et al. (113) reported on 209 children from the Thoratec Registry who were supported with pulsatile Thoratec device for a mean duration of support of 44 days, with survival to transplant or recovery of 68%. Most recently, as adult pump technology transitions to a greater use of continuous flow pumps, particularly the HeartMate II (Thoratec Corp) with decreased adverse events and improved survival, it is not surprising that there have been recent reports of this device in children (115). The Intermacs registry reports on 74 patients <21 years of age, which improved competing outcomes (Fig. 21.7) of adult VADs in older adolescents and young adults (116). The CentriMag (Levitronix, LLC) has also been approved for temporary support and has been successfully employed in a small number of children (117,118). Other continuous flow pumps that have been used in pediatrics

include the Impella LP 5.0 (119) (Abiomed, Danvers, MA), the TandemHeart (cardiac Assist, Inc.), the Heartware (120) (HeartWare, Inc.), and the DeBakey VAD Child (121) (Micromed, Inc.).

VAD Support for Neonates, Infants, and Small Children

An early development in pediatric circulatory support has been the development of an implantable axial flow device, DeBakey VAD *Child* (MicroMed Technology, Inc., Houston, TX), which was granted Humanitarian Device Exemption (HDE) status by the Food and Drug Administration (FDA) and became available for use in small children in 2004. This pediatric device employs the same continuous axial-flow pump used in the adult version with design modifications aimed at reducing the lateral space requirements for device implantation. Under the current HDE, the VAD *Child* is used to provide temporary left ventricular support as a bridge to cardiac transplantation for children from 5 to 16 years of age with a BSA 0.7 to 1.5 m² and is designed to be fully implantable in this size range. Although the clinical experience has been limited (121,122), this device has been used successfully in a small number of children since its introduction.

Currently, there are two pulsatile VAD systems that are suitable for the entire age range of pediatric patients: MEDOS HIA VAD (MEDOS Medizintechnik AG, Stolberg, Germany) and the Berlin Heart VAD (Berlin Heart AG, Berlin, Germany). Importantly, both devices can be used in neonates and infants, and for this reason, are currently the only alternatives for longer-term VAD support in these patients. Both are paracorporeal systems that employ pneumatically driven, thin membrane pumps to provide pulsatile flow. Both systems are available in a variety of pump sizes (10 to 80 mL), with the smallest pump sizes suitable for infant support. A measured amount of compressed air delivered through a pneumatic line compresses the ventricular chamber or bladder, thereby enforcing ejection of blood (Fig. 21.8). Diastolic pump filling is achieved by negative pressure suction. In general, pump rates are kept

Figure 21.7. Outcomes of pediatric and young adult patients implanted with adult devices in the current era: Intermacs Registry 2011.

low, 60 to 80bpm, and negative pressure 40 to 60mm Hg in order to allow for complete filling. The systolic drive pressure is set at 20 to 30mm Hg more than the patient's systolic pressure. The power source generates positive and negative pressures to move the membrane that separates the blood chamber from the air chamber. This membrane appearance can be evaluated at the bedside to ensure minimal wrinkling

Figure 21.8. Mechanics of pneumatically driven, pulsatile, paracorporeal systems. Blood from the patient enters the pump in diastole, in the presence of gravity and/or negative pressure suction, resulting in a concave membrane. Compressed air from the console then enters from the drive unit, resulting in the convex membrane and resulting in systolic ejection of the blood back to the patient.

(Table 21.7). Insufficient filling (more wrinkles noted in convex position) requires an assessment of preload, intrathoracic pressures, and/or tamponade, or an increase of the diastolic drive pressure (i.e., more negative). In the case of inadequate ejection or stroke volume (wrinkles in concave position), assessment should be made of possible sources of increased pulmonary or systemic vascular resistance (afterload) such as inadequate sedation, ventilatory status, and infection. When this is noted, additional support of the circulation with vasodilators and/or inotropes to augment stroke volume should be considered. Because of the high resistance of the small-bore cannulae in small children, positive pressures up to 350 mm Hg and negative suction of 100 mm Hg at pumping rates of up to 180 bpm may be necessary, increasing the power requirements for the driving unit considerably, although at these maximal settings, there may be considerable blood trauma and hemolysis. In this instance, it may be critical to reevaluate the cannula position and cardiac function either by echocardiography or by cardiac catheterization. The changes in setting of the pulsatile devices need to be reassessed only with changes such as intubation or extubation, and once the patient is ambulatory. Otherwise, settings will remain relatively stable throughout the patient course. Inlet and outlet valves are trileaflet and constructed from polyurethane, and while they function well to prevent regurgitation, they remain a potential nidus for thrombus formation, which requires at least twice-daily assessment.

Reports of the Berlin Heart Institute (123–126) have shown results from 1990 to 2006, with 74 patients supported with a mean age of 7.6 years and an initial mortality of 41%. In this cohort, there was a significant era effect, with 74% survival from 200 onwards. Patients could be mobile with the Berlin Heart but had to manage movement of a large console while ambulating. The first North American use of the Berlin Heart was in 2001,

TABLE 21.7 Algorithm for Pulsatile VAD Pump Troubleshooting**A. Inadequate filling (wrinkles in convex position)**

- Assess preload, monitor:
 - CVP, RAp, LAp
 - Heart rate, arterial blood pressure
 - Maintain adequate preload; volume available at bed space
- Assess changes in intrathoracic pressure with ventilation
- Tamponade: inadequate membrane filling
 - Increased filling pressure (increased CVP)
 - Tachycardia
 - Hypotension
- Consider adjusting diastolic pressure
- Consider adjusting systolic ejection time

B. Inadequate ejection (wrinkles in concave position)

- Increased PVR and SVR (afterload)
 - Assess hemodynamics
 - Consider inotropic support and afterload reduction
 - Consider other factors leading to increased PVR and SVR (i.e., level of sedation, mechanical ventilation, sepsis)
- Consider adjusting systolic drive pressure
- Consider adjusting systolic ejection time

CVP, central venous pressure; RAp, right arterial pressure; LAp, left arterial pressure; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

and by 2004, it had gained widespread use. The current North American IDE trial (127) has completed enrollment and awaits FDA decision concerning approval. The North American IDE study included a primary study population of 48 subjects aged 0 to 16 years, divided into 24 younger subjects with BSAs $< 0.7 \text{ m}^2$ and 24 older subjects with a BSA $\geq 0.7 \text{ m}^2$ to $< 1.5 \text{ m}^2$. The primary effectiveness end point compared this study population to a historically matched ECMO control group compiled from the ELSO registry. The purpose of the study was to determine whether use of the EXCOR Pediatric for bridge-to-transplantation is associated with reasonable assurance of safety and probable benefit such that the EXCOR Pediatric merits approval by the FDA under a HDE. In addition, the study was designed to determine whether the EXCOR Pediatric merits continuation with the current trial design and subject population to prove safety and efficacy for premarket approval. Due to the investigational status and while awaiting FDA decisions, few data are available with regards to the IDE trial.

Single center North American experiences have been reported. Fifteen patients from Toronto (112) with a mean age of 8.8 years were on for an average of 29 days, with three being transitioned from ECMO, and 13/15 surviving to transplant. The St. Louis group (107) reported on nine patients with BiVAD support for an average of 35 days, with 8/9 surviving to transplant. The Great Ormond Street group (128) reported on the smallest patients with a group of 11 patients with a median weight of 8 kg and a 91% survival to transplant. Lastly, an Italian group (129) noted 10 patients with a median weight of 6.4 kg and average support time of 61 days with a 40% mortality. The worldwide Berlin Heart EXCOR Pediatric experience now includes >950 patients in 123 centers, in 33 countries, with a median age at implant of 2 years and mean duration of device

support time of 75.5 days. The longest support time worldwide has been 1,131 days (Berlin communication) (116).

Morales et al. (116) reported the most recent nationwide database analysis of children in the United States implanted with MCSDs. They noted that use among pediatric hospitals is growing dramatically and suggested that volume of cases may play a role in overall outcomes. This is an important suggestion that will need further investigation. Other areas requiring further investigation (131–134) include transporting patients on mechanical support, comparing VAD and ECMO outcomes, and understanding the complexities of complex congenital patients.

These data support the use of VAD in children while awaiting transplant. The initial learning curve of the sites appears to be universal, although the North American experience may benefit from the lessons already learned in Europe. The results of the IDE trial will be exciting and well received.

Pediatric Device Initiatives

With the rapid increase in use of the Berlin Heart in North America, pediatric mechanical circulatory support has been recognized as an unmet need by the US HHS. The NHLBI initiative in 2004 awarded \$22 million dollars to promote research and development of mechanical support devices in children. Five awards (130) over 5 years (2004 to 2009) marked significant developments in animal models and *in vitro* testing of infant and pediatric flow dynamics, anticoagulation, and biocompatibility interface technology. The continuation of the Pediatric Mechanical Circulatory Support Program is the PUMPKIN program (2010) that was awarded to four program projects with the intent to move these devices into preclinical

and IDE trial phases. These devices currently include two pediatric VAD devices (PediaFlow and Jarvik child and infant) and two oxygenator devices (Ension (135) and Levotronic). These initiatives and the Berlin Heart IDE trial have led to many more company-led endeavors for pediatric mechanical support.

The future challenge will continue to be the trial design and post market data collection for these new devices. It will be imperative to collect registry data on all children implanted with devices in order to understand patient selection, device specifics, adverse event profiles, and the heterogeneous nature of patient and device-specific variables. Collaboration among clinicians, the FDA, NIH, and industry will be critical in order to continue to move the field forward.

Cardiopulmonary and Right-Left Heart Interactions

Andrew N. Redington

The singular function of the right ventricle (RV), left ventricle (LV), and the lungs is discussed elsewhere. Nonetheless, particularly in the field of congenital heart disease, we are becoming increasingly aware of the importance of the interactions between them. There is continual cross talk between the two sides of the heart, and in turn, the ventricles are continually responding to subtle changes occurring within the thorax as a whole. In this chapter, these interactions, and their modification by congenital heart disease and its surgical repair, are discussed.

COMPARISON OF RIGHT AND LEFT HEART HEMODYNAMICS

The average cardiac output from the RV must, of course, essentially equal the cardiac output from the left heart. Nonetheless, the mechanism by which this is achieved is very different. The RV performs approximately one quarter of the external mechanical work compared with its left ventricular (LV) counterpart. External mechanical work is a function of stroke volume and developed ventricular pressure, and is more accurately described as the area enclosed by the ventricular pressure–volume curve. Figure 22.1 shows a schematic comparison of left and right ventricular (RV) pressure–volume curves. Not only is the developed pressure substantially lower in the RV but its trapezoidal shape still further reduces the amount of work performed on the circulation to generate the cardiac output. The LV essentially works as a square wave pump, its stroke work being reasonably well represented as a direct product of its stroke volume and developed pressure (stroke work = stroke volume \times peak left ventricular pressure–minimum left ventricular pressure). Because of its ability to eject blood into the pulmonary circulation during both pressure rise and pressure fall (1), the external work performed by the RV cannot be described using such a simple derivation. Furthermore, it can be seen that small changes in hemodynamics might impose a major change to global workload of the RV. Indeed, small changes in RV afterload can lead to major changes in workload and the shape of the pressure–volume characteristics to mirror the LV (2).

The trapezoidal shape of the RV pressure–volume relationship is exquisitely matched to the low hydraulic impedance imposed by the pulmonary vascular bed. Unlike the systemic vascular resistance, which reflects a dynamic balance between vasodilatory and vasoconstrictor influences, the pulmonary vascular bed appears to be maximally vasodilated. The low pulmonary vascular resistance requires a healthy endothelium and normal lung function for its integrity. In health, additional inhaled nitric oxide, for example, fails to lower the pulmonary vascular resistance, suggesting pulmonary endothelial vasodilatory capacity is at its maximum (3). This is a markedly different mechanism to that of the systemic vascular bed where a wide

portfolio of vasodilatory substances can lower its resistance. The pulmonary vascular bed is also uniquely affected by external factors. The status of lung inflation, even the normal circulation, has major effects on the pulmonary vascular resistance and hemodynamic function. Normal respiration, ventilating around functional residual capacity, minimizes the pulmonary vascular resistance. Underinflation of the lungs leads to an increased pulmonary vascular resistance, as a result of atelectasis and secondary alveolar hypoxemia, and overinflation of the lungs leads to an increase, secondary to alveolar stretch and direct vascular compression (Fig. 22.2) (4). Both should be avoided whenever RV afterload needs to be minimized.

CARDIOPULMONARY INTERACTIONS IN THE NORMAL CIRCULATION

Descent of the diaphragm during normal inspiration leads to a modest fall in pleural pressure (3 to 5 cm of water) (5) and a concomitant rise in intra-abdominal pressure. These two changes lead to increased venous return and an increased RV stroke volume, in accord with the Frank Starling mechanism. There is thus a waxing and waning of cardiac output of approximately 10% to 15% during the cardiac cycle (6).

The classic experiments of Cournand in the 1940s (7) were interpreted as confirmation that right heart filling and cardiac output were related to intrathoracic pressure. Positive-pressure ventilation via a mask in conscious volunteers led to a fall in cardiac output of approximately 10% to 15%. This was initially thought to be entirely due to changes in systemic venous return (and reduced ventricular preload) imposed by a raised mean intrathoracic pressure. It has subsequently become clear that reduced preload, as a result of increased airway pressure, is not the whole story. In an elegant series of experiments in dogs, Henning (8) showed that restoration of preload during positive-pressure ventilation failed to restore cardiac output to its baseline levels. The persistent reduction in RV stroke volume, despite normalized preload, suggested an adverse effect on intrinsic RV performance. It was hypothesized that the RV shows signs of reduced systolic function, even under the circumstances of a modest hemodynamic burden imposed by lung hyperinflation, as a result of increased afterload occurring via the mechanism described in Figure 22.2. No matter what the mechanism, however, the functional implications of these changes are not simply theoretic. In a study of children undergoing cardiac catheterization performed by Shekerdemian et al. (9), a negative-pressure cuirass device was used to mimic normal ventilation to compare the effects of positive-pressure and negative-pressure ventilation on cardiac output. In essentially normal children having undergone closure of a small arterial duct, for example, there is an approximate 16% fall in cardiac output, simply as a result of a modest

Figure 22.1. Schematic representations of right (shaded) and left ventricular pressure-volume relationships. The external stroke work of the right ventricle (RV; area enclosed by loop) is markedly lower than the left ventricle (LV) (see text for details).

rise in mean airway pressure (to ~8 cm of water) secondary to positive-pressure ventilation. These adverse hemodynamic effects of increased RV afterload (negative cardiopulmonary interactions) become even more important when the right heart circulation is affected by congenital heart disease.

Cardiopulmonary Interactions in Congenital Heart Disease

Given that normal right heart function is dependent on a low RV afterload, normal ventricular preload, and maintained RV systolic function, it would be surprising if congenital heart diseases did not have major effects on its performance. This is indeed the case.

Reduced Right Ventricular Contractile Performance

It has long been known that RV ischemia, in the setting of atherosclerotic coronary disease, is an extremely poorly tolerated hemodynamic burden (10). This, in part, is related to adverse right-left heart interactions (see below), but illustrates the importance of RV contractile performance, even in the presence of a relatively normal pulmonary vascular bed. A more common scenario in congenital heart disease is the adverse effect of cardiopulmonary bypass on right heart function. Brookes et al. (11) showed that even a brief period of cardiopulmonary bypass and cardioplegic arrest, during coronary bypass surgery, leads to a significant decline in RV systolic performance, as assessed by end-systolic elastance. This translates to an even greater dependence on cardiopulmonary interactions in children undergoing congenital heart surgery. Shekerdemian (9), in the study described above, showed that positive-pressure ventilation had an even greater adverse effect in such patients. Compared with negative-pressure ventilation, there was on average a 25% fall in cardiac output with positive-pressure ventilation in children on the intensive care unit after simple right heart surgery (ventricular septal defect [VSD], atrial septal defect [ASD], etc.).

CARDIOPULMONARY INTERACTIONS AND THE ABNORMAL RIGHT HEART

The potential for beneficial and adverse cardiopulmonary interactions is greater when the right heart is intrinsically abnormal because of congenital anomalies or is primarily affected by surgery. There are two circumstances in which these concepts are exemplified, those patients with abnormal RV diastolic function and those with exclusion of the RV from the venopulmonary circulation.

Abnormal Right Ventricular Diastolic Function

It is now known that restrictive RV physiology is a common sequel of surgery for hypoplasia of the right heart, for

Figure 22.2. Effect of lung inflation on pulmonary vascular resistance. Resistance is at its nadir when the lung is at functional residual capacity.

example, pulmonary atresia with intact ventricular septum (12), and after repair of tetralogy of Fallot, for example. The characteristic physiology of these patients is the presence of antegrade diastolic pulmonary blood flow during atrial systole. This occurs when the resistance to RV filling exceeds the pulmonary vascular resistance. Atrial contraction ejects blood through the tricuspid valve, but there is little or no RV filling as the blood passes through the RV (which acts as a passive conduit) to the pulmonary artery (PA). Consequently, up to one-third of the antegrade pulmonary blood flow, and therefore cardiac output, is dependent on atrial systole. Furthermore, this flow is generated by only modest pressure transients (1 or 2 mm Hg) between the right atrium (RA) and the PA in diastole. Clearly a low pulmonary vascular resistance is crucial for this source of cardiac output to be maintained. An important element of the total pulmonary resistance, as discussed above, is the mean airway pressure. Indeed, antegrade diastolic flow is often entirely abrogated during positive-pressure inspiration. Conversely, negative-pressure ventilation may have a major beneficial effect on cardiac output. In postoperative tetralogy patients, positive-pressure ventilation reduces cardiac output by >30% compared with that achieved during negative-pressure ventilation with a cuirass device (13).

The influence of cardiopulmonary interaction is even more impressive when one considers right heart bypass procedures. Here, resting and exercise pulmonary blood flow is markedly dependent on the work of breathing. In our earlier Doppler studies, the phase relationship between ventilation and pulmonary blood flow was shown clearly in both the venopulmonary and atriopulmonary Fontan circulations (14,15). Subsequently, MRI studies have suggested that well over one-third of the cardiac output occurs as a direct result of the work of breathing (16). This may be even more important during exercise (17), particularly in those with total cavopulmonary anastomosis. Positive-pressure ventilation in the Fontan circulation has long been known to adversely affect cardiac output. In early studies of the use of positive end-expiratory pressure, a linear relationship between positive end-expiratory pressure and cardiac output was demonstrated (18). Unsurprisingly, negative-pressure ventilation under these circumstances can lead to a marked increase in cardiac output compared with positive-pressure ventilation. In a separate series of studies, Shekedemian et al. (19) showed the profound effects of positive and negative pressure ventilation on the pattern of pulmonary blood flow in the Fontan circuit (Fig. 22.3) as

Figure 22.3. The effects of negative-pressure ventilation (NPV) on the pattern of pulmonary blood flow after total cavopulmonary connection. Each negative pressure breath is associated with massive augmentation of pulmonary blood flow, an effect abolished when the ventilator is switched off (no vent).

well as on total cardiac output measured by respiratory mass spectrometry.

These studies and others have reinforced the desirability of normal ventilation in such circulations, and this, wherever possible, should be established as early as possible after surgery. In those requiring positive-pressure ventilation, efforts to reduce the mean airway pressure will reap benefits in terms of changes in cardiac output. Thus, minimizing positive end-expiratory pressure, shortening the inspiratory time, and reducing the airway pressure plateau time will all help to reduce the hemodynamic burden on the right heart. Clearly this must not be at the expense of alveolar ventilation (to avoid hypercapnic pulmonary vasoconstriction) or alveolar inflation (to avoid hypoxemic vasoconstriction).

Exclusion of the Right Ventricle

Because of the very marked changes in RV hemodynamics imposed by progressive pulmonary hypertension or RV outflow tract obstruction, the effects of subtle changes in airway pressure on RV intrinsic contractile performance are much less marked. Indeed, one can consider the pressure-volume relationships of the hypertensive RV to be similar to those of the normal LV (2). Consequently, while changes in preload will continue to occur, the effects of afterload are much less marked. Also, it should not be forgotten that the adverse effects of positive-pressure ventilation on the right heart are in contradistinction to those on the left heart, particularly the failing LV.

CARDIOPULMONARY INTERACTIONS AND THE LEFT HEART

Although the manifestations are different, the LV is also subject to cardiopulmonary interactions and the effect of mean airway pressure on its function. Although in general the effects of increased mean airway pressure are largely adverse on the right heart, they are largely beneficial on the left heart. This is because the total afterload of the LV (transmural pressure) is reduced by increased mean airway pressure (20). Although essentially insignificant to the normal LV, such changes can provide beneficial effects, for example, in dilated cardiomyopathy. Indeed, continuous positive airway pressure (CPAP) has a multitude of beneficial effects to the failing left heart (21). By increasing alveolar pressure, the transalveolar gradient for edema formation is reduced. Furthermore, the afterload of the LV is also reduced, improving its ejection fraction and stroke volume. Although relatively infrequently used in pediatric practice, CPAP masks have proven to be particularly useful in the dilated cardiomyopathy of ischemic and acquired heart disease in adults (22), and such therapy merits further investigation in children.

RIGHT-LEFT HEART INTERACTIONS

It has been traditional to examine LV and RV function as separate entities. Nonetheless, the last two decades have seen an explosion in our understanding of the ways in which the two sides of the heart interrelate and contribute to each other. Not only is this a manifestation of its shared cavity, the pericardium, but also the recognition of shared myofibers that can neither be defined as exclusively LV or RV (23). Thus, the

function of the LV has profound effects on the function of the RV, and vice versa, both in health and disease.

The Effects of the Left Ventricle on the Right Ventricle

The classic experiment of Damiano et al. (24) in 1991 confirmed the presence of substantial cross talk between the ventricles in health. Albeit in an experimental model, the effects of LV performance on RV force generation were clearly demonstrated. In their exquisite study, the electrically isolated but mechanically contiguous ventricles were examined during individual chamber pacing (Fig. 22.4). Under these circumstances, pacing the RV led to virtually no mechanical effects on the left side of the heart. Pacing the electrically isolated LV, however, led to almost normal RV pressure development. It appears, therefore, that the geometric change, consequent on LV shortening, imposes a major mechanical effect on the RV. The crescent-shaped free wall, wrapped around the ventricular septum and contiguous with the LV free wall, is presumably deformed to generate a RV pressure. This effect appears to be largely independent of the RV free wall function. In another set of experiments, Hoffman et al. (25) showed that replacement of the RV free wall with a noncontractile patch was still associated with significant RV pressure generation during LV contraction. Overall, it has been estimated that over one-third of the work performed by the RV is a direct consequence of LV shortening. It might be possible to harness this ventricular-ventricular cross talk to improve biventricular function. In animal experiments, aortic constriction, leading to an increase in LV afterload and work, was shown to increase RV stroke volume, again as a result of the cross talk phenomenon (26).

The Effects of the Right Ventricle on the Left Ventricle

In the experiments by Hoffman et al. (25) described above, the effect of LV shortening on RV pressure development in a model of RV free wall replacement was described. This experiment also showed that as the size of the artificial RV was increased, there appeared to be an adverse effect on LV mechanical function. As the RV dilated, LV pressure development fell. Whether this was a parallel effect (reflecting adverse ventricular cross talk) or a series effect (reflecting reduced cardiac output from the RV and therefore reduced preload to the LV) could not be determined in these experiments. In the mid-1990s, Brookes et al. (27) aimed to dissect out these influences in a porcine model. Isolated RV ischemia was used to induce acute right heart dilation, during which RV and LV contractile performance was measured using end-systolic elastance derived from pressure-volume analysis. It was shown that RV dilation imposes adverse effects on LV mechanical performance directly, presumably owing to geometric changes influencing LV contractile efficiency. These effects were more manifest when the pericardium was intact, supporting this hypothesis.

It would be naive to assume that all of these effects are manifestations purely of systolic interactions. Independent of major changes in contractile performance, adverse diastolic ventricular-ventricular interaction is frequently encountered. Primarily a manifestation of septal shift toward the LV in early diastole, pulmonary hypertension, for example, leads to reduced LV early diastolic filling velocities and increased dependence on atrial systole (28).

The superimposition of congenital heart disease and the effects of surgical correction further amplify these ventricular-ventricular effects and are discussed below.

Figure 22.4. This study demonstrates the passive effect of active contraction of the contralateral ventricle (see text for details). Ventricular-ventricular interaction is shown clearly in the **top right-hand panel**. There is almost normal right ventricular pressure development when the left ventricle (LV) contracts, even though the right ventricle (RV) is electrically isolated. (Redrawn from Damiano RJ Jr, La Follette P Jr, Cox JL, et al. Significant left ventricular contribution to right ventricular systolic function. *Am J Physiol* 1991;261:H1514–H1524, with permission.)

Right-Left Heart Interactions in Congenital Heart Disease

It is likely that all congenital heart diseases have more or less subtle abnormalities of ventricular-ventricular interaction. However there are some major, clinically significant interactions that bear more detailed analysis. These can loosely be described as functional and geometric and are discussed in detail below.

Functional Interactions

Surgery to the RV outflow tract almost invariably leads to some degree of residual pulmonary regurgitation, and it is now well known that this ventricular volume load leads to RV dilation in most patients. The effects of pulmonary regurgitation after repair of tetralogy of Fallot are probably the best described examples of this phenomenon. Although our understanding of the effects of right heart dilation under these circumstances has evolved over the last 15 years, it is only in the last 5 years that the biventricular effects of this problem have become apparent. Several studies have now shown a loose but linear relationship between RV ejection fraction and LV ejection fraction late after repair of tetralogy of Fallot (29,30). Furthermore, those with overt biventricular dysfunction have a worse outcome compared with those without (30). Not only are ventricular-ventricular interactions important in terms of global function, but abnormalities of ventricular-ventricular timing may also have significant adverse effects. D'Andrea et al. (31) have explored this phenomenon in a recent study analyzing the dyssynchrony between the ventricles. They studied the onset of RV and LV contraction in patients after repair of tetralogy of Fallot, showing a worse exercise tolerance and an increased frequency of arrhythmia in those with significant ventricular-ventricular delay.

It is likely that subtle regional abnormalities will also have significant biventricular effects. Regional wall motion abnormalities have been described in virtually all congenital heart diseases (32,33). They are also almost always associated with decreased global performance and therefore likely biventricular effects. It remains to be seen whether this intraventricular and interventricular incoordination will be responsive to interventions such as biventricular pacing, but early data appear promising (34).

Geometric Interactions

Unlike the more directly functional interaction described above, acute changes in geometry can modify functional per-

formance of both sides of the heart, particularly in congenital heart disease. Acute right heart dilation not only affects RV performance, but also induces LV dysfunction via systolic and diastolic interactions (see above).

More chronic geometric changes can lead to unique abnormalities in the setting of congenital heart disease. The systemic RV is particularly susceptible to such changes. Here, the morphologic tricuspid valve is the systemic atrioventricular valve and is characterized by its septal papillary muscle and chordal attachments. It is now well recognized both under the circumstances of surgical repair of simple transposition and in the setting of congenitally corrected transposition that septal shift makes a significant contribution to the development of tricuspid regurgitation in these hearts. Conversely, efforts to modify this septal shift can produce profound improvements in the degree of tricuspid incompetence. Figure 22.5 shows just such a change. The right-hand panel from this patient with congenitally corrected transposition shows a dilated RA and hugely dilated morphologic left atrium as a result of severe tricuspid valve incompetence. The left-hand panel shows minimal tricuspid incompetence in the same heart, just 20 seconds later. The reduction in tricuspid regurgitation and the remarkable change in left atrial (LA) size have occurred as a consequence of PA banding. Elevation of LV pressure to modify septal geometry restored tricuspid valve competence in this patient. This phenomenon has been demonstrated in patients after the Mustard procedure (35) as well as in patients undergoing LV retraining in the setting of congenitally corrected transpositions. It is beyond the scope of this chapter to discuss the advisability, prerequisites, and methods for evaluation of LV retraining under such circumstances, but by its effects on tricuspid incompetence, PA banding alone may be destination therapy for some of these patients.

CONCLUSIONS

Important cardiopulmonary and ventricular-ventricular interactions are intrinsic to normal cardiovascular physiology. The consequences of these effects are amplified by disease in the structural normal heart and may be profound when the heart is modified by congenital anomalies. Our understanding of the effects of congenital heart disease on cardiopulmonary and ventricular-ventricular interactions continues to evolve, but we have learned that description of functional performance in any patient is incomplete without their consideration.

Figure 22.5. The acute effects of pulmonary artery (PA) banding on tricuspid valve regurgitation in congenitally corrected transposition. Left ventricular (LV) hypertension induces septal shift toward the systemic right ventricle (RV), leading to restoration of tricuspid leaflet apposition by its effect on its septal attachments. As a result, the left atrial (LA) size is markedly reduced. RA, right atrium.

Gary A. Smith ■ Timothy F. Feltes

Traumatic injury to the heart occurs when energy is transferred to the heart in amounts or at rates that exceed the tissue's threshold to withstand it, resulting in structural damage or functional abnormality. The transfer of injurious energy is most commonly associated with blunt trauma, penetrating trauma, or contact with electrical current. Most medical knowledge about cardiac trauma in children is extrapolated from studies of adults. Relatively little direct information is available regarding cardiac injuries in children.

BLUNT CARDIAC INJURY

Blunt trauma accounts for the vast majority of injuries to children and is the chief cause of cardiac trauma in the pediatric age-group. The incidence of cardiac injury in blunt trauma among children has been reported to be from 0% to 43% (1). Blunt cardiac injuries are often unsuspected injuries associated with multiple system trauma. Clinical manifestations of cardiac trauma vary depending on the location of injury. They are often nonspecific and include shock, cardiovascular instability, dysrhythmias, chest pain, and changes in mentation. In victims of multiple trauma, all of these findings can be easily attributed to other serious injuries to the head, abdomen, or extremities.

Parmley et al. (2) performed autopsies on a large series of motor vehicle crash victims and found that blunt cardiac injury was one of the most frequently missed diagnoses. This finding has been corroborated by others. Having a high level of suspicion for blunt cardiac injury is necessary for early diagnosis and intervention. The autopsy series of Parmley et al. (2) described various mechanisms of nonpenetrating cardiovascular injury (Table 23.1).

Most blunt cardiac injuries from direct chest impact among children are the result of motor vehicle crashes (3). Blunt blows with weapons, fists, and animal kicks; blunt collisions during sports; and falls from heights also cause direct-impact cardiac injuries.

Because the heart is suspended from the great vessels, acceleration-deceleration injuries occur as the heart moves like a pendulum in the thorax. Traction on the great vessels can cause tears at their points of fixation.

Compression of the chest can crush the heart or cause damage through increased intrathoracic and intracardiac pressures. Cardiac rupture is more likely if compression occurs during maximum filling of the chambers. Rib fractures and contusions of the chest wall are not always seen, especially in children owing to their highly compliant chest walls. Abdominal and lower extremity compression also can force blood back to the heart, causing damage through a hydraulic ram effect.

Commotio cordis is a specific form of cardiac trauma that has become an increasingly recognized cause of sudden

cardiac death in otherwise healthy young athletes (4). While the National Commotio Cordis Registry in Minneapolis lists almost 250 cases of commotio cordis, the frequency of such cases is most certainly underestimated (5). Commotio cordis is a form of nonpenetrating chest trauma insufficient to result in significant myocardial or chest wall injury. The most likely mode of death appears to be an induction of a malignant arrhythmia (i.e., ventricular fibrillation) due to the transfer of concentrated mechanical energy (concussion) to the heart resulting in electrical instability. The two critical components appear to be precordial impact location and the timing of the impact occurring during the upstroke of the T wave (6–8). The impact site for victims of commotio cordis is specifically located at or near to the center of the cardiac silhouette. Recent animal model studies suggest that the trauma must occur within an electrical vulnerability period during the cardiac cycle, namely, within 20 milliseconds of the T-wave upstroke.

As reported recently by Maron and Estes (4), commotio cordis is seen most frequently in the second decade of life, peaking at 15 years of age. Baseball is the most common sport in which commotio cordis is observed followed by softball, hockey, and football. It is more commonly experienced during organized sporting events but by no means exclusively. In younger victims (<10 years of age) commotio cordis may occur during activities unrelated to sports.

Victims of commotio cordis most commonly experience instantaneous cardiovascular collapse but in approximately 20% of cases victims are able to stay erect for several seconds after the trauma occurs. Survival from resuscitative efforts is low but has increased to 35% in recent years most likely due to increasing availability of automatic external defibrillators and bystanders knowledgeable in the use of these devices.

According to data from the above-mentioned national registry, nearly one-third of cases of commotio cordis that occurred during competitive sports were victims who were wearing a commercially available chest protector. Many of these devices were not designed to prevent commotio cordis and either expose the precordium or do not adequately absorb the impact from a projectile (9). Efforts have been made to create safer baseballs (aka “safety” baseballs) with some evidence of effectiveness. Some sports now require protective equipment (10). See Table 23.2 for features differentiating cardiac concussion from cardiac contusion (11). It is important that the public and organizers of sporting events be aware of the risk of commotio cordis.

Two other mechanisms of blunt cardiac injury have been described: Blast injury and a combination injury, which involves more than one of the above mechanisms.

The types of anatomic injuries resulting from these various mechanisms in blunt cardiac trauma include pericardial injury, myocardial contusion, cardiac rupture, septal disruption, ventricular aneurysm, injury to the heart valves and supporting

structures, and injury to the great vessels, brachiocephalic arteries, venae cavae, and coronary arteries (Table 23.3).

Pericardial Injury

Blunt pericardial injuries range from contusion to rupture and are usually associated with myocardial injury. Isolated pericardial injuries are rare. Pericardial lacerations and pericardial rupture are rarely significant injuries unless cardiac herniation occurs through a pericardial tear. Cardiac herniation can result in severe circulatory compromise and rapid death. Cardiac tamponade is a common complication of myocardial injury but is not likely with isolated pericardial injury.

Traumatic pericarditis can develop after pericardial contusion. A chronic pericarditis after cardiac trauma can last 1 to 4 weeks. The clinical features are single or recurrent pericardial or pleural effusions, similar to the postpericardiotomy syndrome.

The frequency of pericardial injury associated with blunt chest trauma is unknown. Asymptomatic pericardial effusions have been demonstrated by cardiac ultrasonographic examination following blunt chest trauma. Pericardial lacerations were frequently found in dogs following sublethal blunt chest trauma. The most frequent manifestations of traumatic pericarditis include pericardial friction rub and nonspecific electrocardiographic (ECG) ST-T wave changes and diffuse low voltages.

Traumatic cardiac tamponade rarely presents with all the classic Beck triad features of hypotension, distant heart sounds, and elevated central venous pressure with neck vein distension. An echocardiogram is the most sensitive diagnostic test for cardiac tamponade and can be used in the emergency department for selected trauma patients. A diagnostic and therapeutic pericardiocentesis also can be used for patients with suspected cardiac tamponade. However, false-negative pericardiocentesis results have been observed in 25% to 80% of patients who have blood in the pericardium (12).

Treatment of traumatic pericarditis is based on symptoms. If pericardial effusion or associated pleural effusions are clinically significant, pericardiocentesis or thoracocentesis is indicated. Chronic pericarditis or postpericardiotomy syndrome is treated with anti-inflammatory agents.

Most pericardial lacerations are incidentally found during thoracotomy being performed for other indications and are not repaired unless the defect is large enough to pose a risk of cardiac herniation. Large pericardial lacerations that are difficult to repair may be managed by pericardiectomy.

Myocardial Contusion

Myocardial contusion in the general population is most often a result of direct blunt force to the chest during motor vehicle

TABLE 23.2 Differential Features of Cardiac Concussion and Contusion

Feature	Concussion	Contusion
Force	Sharp, not necessarily violent	Generally violent
Direction of force	Sternum to vertebra	Of no significance
Onset	Immediate	Gradual
Course	Transitory	Persisting
Loss of consciousness	Usually	Not characteristic
Disturbances of rhythm and conduction	Characteristic, immediate	Absent or delayed
Changes in ST segment and T waves	Nonspecific	Anatomically localized injury or ischemia

crashes, industrial injuries, farm injuries, or sports injuries. The reported incidence of myocardial contusion associated with major trauma varies between 3% and 76% depending on the study population and the diagnostic criteria (13,14). Approximately one-third of children with cardiac contusion may have no external evidence of chest injury. ECG abnormalities and dysrhythmias are less common in these children than in adults who have cardiac contusion.

The first reported case of autopsy-proven myocardial contusion was in 1764; it described a boy struck in the chest by a plate (15). Recognition of cardiac contusion is difficult because of nonspecific clinical findings and lack of an accurate diagnostic test (3). The findings of cardiac contusion are easily attributed to other serious injuries that are often present. Predicting which cases will be clinically significant has not been possible, thus complicating the discussion about appropriate management of myocardial contusion. The diagnosis of myocardial contusion should be considered in any child with significant blunt chest or multiple system trauma.

Most cases of myocardial contusion are mild and asymptomatic, and go unrecognized, but complications can be serious. Complications of myocardial contusion include dysrhythmias, conduction disturbances, cardiac failure, aneurysms, pseudoaneurysms, myocardial wall thinning, cardiac rupture, and cardiac arrest. Most are late findings. Underlying cardiac disease, including ischemia, cardiomyopathy, or congenital heart disorders, increases the risk of complications from blunt cardiac injury. The pathologic findings of myocardial contusion include myocardial hemorrhage, myocardial fiber necrosis, and, later, fibrous scar formation.

The diagnosis of myocardial contusion can generally be made in patients with blunt chest trauma if the ECG demonstrates a dysrhythmia or changes compatible with ischemia or contusion, the creatine phosphokinase-muscle band (CPK-MB) fraction is $>5\%$ of the total CPK, and the echocardiogram is abnormal (16). However, ECG findings in cardiac contusion are nonspecific, and false-positive results can occur. Because CPK-MB is also present in skeletal muscle, pancreas, and bowel, extensive skeletal muscle or abdominal trauma can cause elevation of CPK-MB. In addition, CPK-MB has been shown to have a low sensitivity and specificity for cardiac injury in some studies (17,18). Lactate dehydrogenase isoenzymes and serum glutamic oxalotransaminase are of no value in the diagnosis of cardiac contusion. Troponin I and T have been shown to be accurate indicators of myocardial injury that may aid in the diagnosis of myocardial contusion (19–21). In adult studies, the positive predictive value of elevated cardiac troponin T ranges from 20% to 100% and the negative predictive value ranges from 74% to 100% (22–23). Diagnostic sensitivity may be improved by use of recently developed highly sensitive cardiac troponin assays, but validation studies have not yet been reported (24).

The echocardiogram may be more useful than serial ECGs or cardiac isoenzyme measurements in evaluating blunt cardiac injuries because it can detect pericardial effusion, valvular dysfunction, septal defects, enlarging chambers, and wall motion abnormalities and can be used to determine ejection fraction. Echocardiographic abnormalities are detected in 20% to 47% of patients following blunt trauma (25). Transesophageal echocardiography may offer advantages over transthoracic echocardiography, especially in obese patients. The proximity of the esophagus to the thoracic aorta and atrioventricular (AV) valves allows clearer visualization of injuries to these structures. In the absence of ECG abnormalities or cardiac isoenzyme elevation, cardiac dysmotility on echocardiogram is not associated with adverse patient outcome (26).

Gated radionuclide angiography is a useful method for detecting abnormalities of cardiac function. It has been applied in the evaluation of blunt cardiac trauma to detect

diminished ejection fractions, hypokinetic wall segments, and ventricular aneurysms. The most common finding it identified in adult patients with blunt chest trauma was mild hypokinesis of the right ventricular wall with diminished ejection fraction. Unfortunately, gated radionuclide angiography is not predictive of morbidity and mortality in cardiac contusion.

Following blunt chest trauma, patients with abnormal ECGs require admission, continuous cardiac monitoring, and evaluation of cardiac isoenzymes. Cardiac monitoring should continue until abnormal ECGs have reverted to normal for at least 24 hours, cardiac isoenzymes have normalized, and stabilization of other major injuries has been achieved. The main treatment goal is avoidance of death caused by dysrhythmias or hemodynamic compromise.

Cardiac Rupture

Although an uncommon injury, cardiac rupture is estimated to cause 10% to 15% of adult motor vehicular crash fatalities. Two-thirds of deaths owing to cardiac rupture occur at the scene (27). Cardiac rupture occurs most commonly in young male drivers suffering precordial steering wheel impact during a crash (28). Ventricular rupture is more common than atrial rupture, and the thin-walled anteriorly positioned right ventricle is more commonly ruptured than the left ventricle. Multiple chamber rupture is not uncommon in these cases, as is combined cardiac rupture and aortic rupture, reflecting the large amount of force involved in these injuries (2).

Ventricular rupture can result from direct cardiac compression or from an indirect hydraulic ram effect that occurs during abdominal or extremity compression. During late diastole, compressing a distended noncompliant ventricle can tear AV valves, chambers, septa, and other cardiac structures. Atrial rupture appears to involve compression of the filled chamber as well as torsion when the AV valves are closed and the chamber is filled during late systole. The atrial appendages are the thinnest portions and most prone to atrial rupture. Delayed ruptures are extremely rare and may follow infarction associated with trauma and gradual softening of the ischemic tissues or rupture of a myocardial aneurysm or pseudoaneurysm (28).

The clinical manifestation of myocardial rupture is usually tamponade, although approximately one-third of patients will have exsanguinating hemorrhage through associated pericardial lacerations. The association of cardiac tamponade with cardiac rupture limits the rate of exsanguination and increases the chances of survival for these patients.

The first surgical repair of blunt cardiac rupture was reported by Des Forges et al. (29) in 1955 involving a 4-cm right atrial laceration. Until then, cardiac rupture had been considered universally lethal. Surviving ventricular rupture secondary to blunt chest trauma is rare. In 1990 the first pediatric survivor was preceded by only three reported adult cases (30).

Septal Disruption

The interventricular septum ruptures most commonly in the muscular portion near the apex, which is the thinnest area of the septum. Any portion of the muscular septum can rupture, even in multiple sites, with concomitant injury to the conduction system. Echocardiography should demonstrate the abnormality. Cardiac catheterization can be performed to determine the magnitude of left-to-right shunt, measure pulmonary artery pressures, and evaluate ventricular function. Ventricular septal defects with significant left-to-right shunts require surgical closure. Disruption of the atrial septum has also been reported (31). Some attempts to close VSDs by

catheter-delivered devices have met with various levels of success (see Chapter 13).

Ventricular Aneurysm

Posttraumatic ventricular aneurysms usually occur as a complication of coronary artery injury, most commonly to the left anterior descending coronary artery (32). In a world literature review by Grieco et al. (32) in 1989, 32 cases of left ventricular aneurysm following blunt chest trauma were reported. Patients ranged in age from 3 to 59 years. Motor vehicle crashes were the principal mechanism of injury. The most common presenting symptoms were congestive heart failure (10 patients), palpitations or dysrhythmias (9 patients), and arterial embolus (5 patients). Seven patients had mild constitutional complaints or were asymptomatic. Time of diagnosis ranged from 5 days to 18 years (median time 3 months) postinjury. Ventricular aneurysmectomy is recommended to avoid lethal complications (32).

Injury to Heart Valves and Supporting Structures

Heart valve rupture from blunt chest trauma occurs infrequently. Nine percent of adult fatalities from blunt chest trauma had cardiac valve injury in the autopsy series by Parmley et al. (2), and nearly all of these cases had other associated cardiac injuries. The aortic valve is the most frequently injured valve followed by the mitral and tricuspid valves.

Valvular injury results from a rapid increase in intracardiac pressure against a closed valve. During late diastole to early systole, the filled chambers experience their highest normal intraluminal pressures. With additional external pressure from forceful compression of the chest, abnormally high pressure is exerted on a closed heart valve. The timing of chest trauma in the cardiac cycle appears to determine which valve is injured. The greater left heart pressure gradients may contribute to the higher frequency of injury to the aortic and mitral valves. Another mechanism by which the aortic valve can be injured is the hydraulic ram effect that occurs when the aortic blood flow reverses during abdominal and lower extremity compression (33).

Presenting signs and symptoms of valvular injury depend on which valve is involved, the degree of valvular insufficiency, and the presence of other associated cardiac structural damage. Surgical valve replacement is generally required for the more severe injuries. Helpful diagnostic tests are the chest radiograph and ECG. The most useful test is Doppler echocardiography, which can identify disrupted blood flow or valvular dysfunction in addition to other associated structural defects.

Great Vessel Injury

Great vessel injury can occur with blunt trauma. The aorta is the most commonly injured great vessel. Injury to the pulmonary artery is rarely reported. Although aortic rupture from blunt trauma can occur with falls, crush injuries, and blast injuries, nearly 70% of cases in the general population occur with motor vehicle crashes. The mechanism of aortic rupture involves the shearing stress of sudden deceleration or sudden increases in intraluminal pressure. Ejected passengers, pedestrians struck by vehicles, and persons who fall from heights have higher risk for aortic rupture than victims of deceleration vehicular collisions. Aortic injury can occur with either horizontal or vertical deceleration (33).

The aorta most commonly ruptures when acceleration-deceleration forces pull a mobile aortic segment away from a point of fixation. The sites usually ruptured are the aortic

isthmus, fixed by the brachiocephalic arteries; the ascending aorta, fixed to the heart at the aortic root; and the descending aorta, fixed at the diaphragm. Tears of the ascending aorta carry a high risk of immediate mortality and are frequently associated with myocardial contusion and aortic valve injuries (2). Autopsy studies show that tears in the aortic isthmus and ascending aorta occur in 45% and 20% of cases of aortic rupture, respectively, but clinical studies show about 90% of aortic tears at the aortic isthmus. Overall, 80% to 90% of persons with motor vehicle-related aortic rupture are dead at the scene (12). Of the 10% to 20% who survive long enough for diagnosis and intervention, 30% die within 6 hours and 50% within 24 hours.

Fortunately, aortic dissections are rare in pediatric patients and are most commonly associated with trauma or a preexisting medical condition (e.g., Marfan, Loeys-Dietz, or Turner syndrome) (34). Management relies heavily on decision making and treatments established in the adult literature (35–37). Uncomplicated aortic dissections of the descending aorta (Stanford type-B) are typically managed conservatively with close heart rate and blood pressure control with the goal to stabilize the dissection. β -adrenergic blockers are the mainstay in this treatment. In complicated type-B dissections (e.g., impaired organ perfusion, loss of pulses) fenestration should be accomplished in the interventional suite or, in rare instances, surgically considered. Endovascular stent grafting has been reported in some types of aortic disruptions but there is little experience in the pediatric age-group. Dissections of the ascending aorta and/or arch (Stanford type-A) require urgent surgical intervention due to the risk of coronary malperfusion or cerebral embarrassment secondary to a dissection extending into the coronary or carotid arteries, respectively.

More common than aortic rupture and transmural aortic tears are superficial aortic tears into the intima and media with blunt trauma. These are generally without serious consequence and are often undiagnosed. Partial tears are infrequent and usually are located posteriorly. Multiple tears occur in 15% to 20% of cases. Traumatic aortic dissection is rare, occurring when the subadventitial layer remains intact and contains a periaortic hematoma (33).

Presenting complaints and physical findings may not accurately predict the presence or absence of aortic rupture. Symptoms may be absent, and visible external injury is not seen in about one-third of cases. Symptoms of aortic rupture include dyspnea, back pain, dysphagia and hoarseness, upper extremity hypertension, or an upper and lower extremity blood pressure differential similar to that seen with aortic coarctation. An aortic insufficiency heart murmur may be heard.

Chest radiographs may show mediastinal widening, a right-sided aortic root prominence, loss of aortic arch sharpness, or rightward deviation of the trachea. Less common radiographic findings include downward displacement of the left mainstem bronchus, rightward deviation of the esophageal nasogastric tube, left hemothorax, the apical cap sign, and first rib fracture. Aortography is considered to be the gold standard and is indicated in all cases of suspected aortic rupture, even if plane radiographs are normal (12). Transesophageal echocardiography, CT scanning, and magnetic resonance imaging also are useful in diagnosing rupture of the aorta.

Brachiocephalic Arteries

The second most common vascular injury with blunt trauma is injury of the brachiocephalic arteries. The mechanism of injury includes horizontal and vertical deceleration, chest compression, crush, distraction, and hyperextension of the shoulder. The resulting arterial injury is similar to that of the aorta. Massive bleeding or ischemia are rare complications (33).

Vena Caval Injury

Similar to aortic injury, vena caval injury is infrequent with nonpenetrating trauma. The abdominal segment of the inferior vena cava is more frequently injured than the chest segment. Because the thin-walled veins do not vasoconstrict like transected arteries after injury, severe hemorrhage and high mortality are usual with vena caval injuries. Mortality is higher in abdominal than in chest segment vena caval injury. Blunt trauma can cause avulsion or tear of the inferior vena cava near the right atrium that can extend into the right atrium. Therefore, associated cardiac injury is common when inferior vena caval injuries are located near the heart (33).

Plane chest radiography is not helpful. The emergent nature of these injuries does not allow time for venography. Therefore, rapid surgical exploration and repair is indicated when vena caval injury is suspected (33).

Coronary Artery Injury

Coronary artery injury from blunt trauma is rare. The study by Parmley et al. (2) of 547 patients who died from blunt chest trauma reported only 10 coronary artery lacerations and no cases of intraluminal thrombosis, even in areas of cardiac contusion. The incidence of coronary artery injury in nonfatal trauma cases is unknown. The most commonly injured coronary artery is the left anterior descending coronary artery. Consequences of coronary artery injury are myocardial infarction, hemopericardium, cardiac tamponade, and coronary artery and ventricular aneurysms and pseudoaneurysms (33).

A review of the English-language medical literature by Neiman and Hui (38) in 1992 reported 40 cases of myocardial infarction associated with blunt cardiac trauma. The pathophysiologic mechanism underlying acute myocardial infarction following blunt chest injuries has not been clearly established. Suggested mechanisms include transient coronary artery spasm, thrombus formation within the coronary artery, coronary artery dissection, or hemorrhage into an atheromatous plaque.

Definitive diagnosis of coronary artery injury is accomplished by angiography. These injuries are underdiagnosed because chest pain associated with blunt chest injury is often attributed to concomitant chest wall contusion, pericarditis, pulmonary contusion, rib fractures, or other associated injuries that are not routinely evaluated by coronary angiography. Coronary angiography is indicated for all blunt cardiac trauma patients with angina or myocardial infarction to determine the status of the coronary arteries and to locate surgically correctable lesions.

PENETRATING CARDIAC INJURY

Although blunt trauma accounts for most injuries among the pediatric population, penetrating trauma is increasing among young adults, teenagers, and even younger children. The ratio of gunshot to stab wounds is also increasing (39,40). With the concomitant improvement in emergency medical services, more patients with penetrating cardiac wounds are now reaching hospital emergency departments.

The first description of penetrating cardiac wounds is found in the Edwin Smith Papyrus, written in 3000 BC. Homer also described penetrating cardiac trauma in *The Iliad*. Baron Larrey, Napoleon's surgeon, is credited with performing the first pericardiocentesis in 1829. It was common wisdom for years that nothing could be done for wounds to the heart until von Rehn performed the first successful cardiorrhaphy in 1896 for a 22-year-old man with a 1.5-cm stab wound to the right ventricle. This was only 13 years following the statement by

Dr. Theodore Billroth that, "A surgeon who tries to suture a wound of the heart deserves to lose the esteem of his colleagues." (41)

The mortality risk for penetrating cardiac trauma is related to a number of factors, including the cause of injury, size of the wound, location of the wound, any associated noncardiac injuries, and length of time from injury to initiation of resuscitative measures.

Gunshot wounds cause much more extensive tissue destruction than stab wounds owing to transfer of large amounts of kinetic energy to the tissues. Not only does a bullet cause greater disruption of myocardium and internal structures of the heart, but the rent in the pericardium is larger, which makes tamponade less likely and exsanguination more rapid. For these reasons, the mortality rate of gunshot wounds to the heart is approximately twice that of stab wounds.

A stab wound is more likely to result in cardiac tamponade than a gunshot wound. More than 80% of stab wounds to the heart present with cardiac tamponade, whereas only 20% of gunshot wounds present in this fashion. Stab wounds are the most common cause of acute tamponade (41,42). The retention of blood within the pericardial sac prevents rapid exsanguination, providing more time for the patient to reach medical care and receive life-saving cardiorrhaphy. This has led some to consider hemopericardium as a mixed blessing. However, if allowed to progress, hemopericardium can lead to fatal cardiac tamponade. Because of its thicker myocardial wall, stab wounds to the left ventricle that measure <1 cm will often spontaneously seal. Stab wounds to the right ventricular wall, however, usually result in cardiac tamponade because the thinner myocardial wall does not usually spontaneously seal. The thinness of atrial walls decreases the likelihood of spontaneous sealing; however, the low intrachamber pressures counterbalance this factor (41).

As is the case with blunt cardiac trauma, the anatomic position of cardiac structures determines their likelihood of injury owing to penetrating trauma. Those structures located more anteriorly are more likely to be injured. In decreasing order of frequency, penetrating cardiac injuries involve the right ventricle, left ventricle, right atrium, and left atrium. For the same reason, the left anterior descending coronary artery is more frequently injured than the right coronary artery (42). Multiple chamber injury has a high mortality rate (43).

Penetrating cardiac injury can occur owing to iatrogenic causes. These injuries most often occur during diagnostic procedures, invasive monitoring, or other therapeutic interventions (40). Other causes of penetrating injury to the heart include ice picks, nonbullet projectiles, swallowed sewing needles, and inward displacement of fractured ribs with chest trauma (44).

Cardiac injury should be presumed to be present until proven otherwise in patients presenting with penetrating wounds of the precordium, neck, axilla, back, or upper abdomen. Beck triad is frequently absent in patients with cardiac tamponade, and determination of jugular venous distension is particularly difficult in young children because of their short necks. Additionally, if there is hypovolemia owing to acute blood loss, increased central venous pressure may not be seen with cardiac tamponade (41).

Penetrating injuries to the chest are frequently associated with intra-abdominal injury. Ten percent to thirty percent of patients with penetrating cardiac wounds also have intra-abdominal injury. This is important because mortality is greater for patients with penetrating cardiac injury associated with intra-abdominal injury than for those with cardiac injury alone (41).

Approximately 60% to 80% of patients with penetrating cardiac wounds die prior to reaching a hospital. For those who arrive in the emergency department with vital signs, or for those who had vital signs at the scene and lost them en route to the hospital, resuscitative intervention must be immediate (45). Diagnostic tests, such as a chest radiograph, are of little use.

Emergency department echocardiography is available at some trauma centers, which has decreased the time to diagnosis of penetrating cardiac injury and has improved survival. Pericardiocentesis can rule in, but not rule out, cardiac tamponade because of the high frequency of false-negative results. Performing a sub-xiphoid pericardial window has been recommended by some to diagnose hemopericardium in selected stable trauma patients.

Initial emergency management of penetrating cardiac trauma is the same for children and adults, following the principles of (a) maintaining a patent airway with adequate oxygenation and ventilation, (b) preservation of adequate tissue perfusion through rapid intravenous or intraosseous administration of fluids and blood, and (c) control of hemorrhage (12).

As with adults, children with a penetrating cardiac wound should receive emergency thoracotomy in the emergency department whenever they are too unstable to be transported to the operating room. Pericardiocentesis must be viewed as a temporizing measure until thoracotomy and definitive cardiorrhaphy can be performed. Emergency department thoracotomy was first described by Beall et al. (46) in 1966 for immediate resuscitation of moribund patients with penetrating chest injuries. The purpose of emergency department thoracotomy is reversal of cardiac tamponade, control of hemorrhage, open chest cardiac massage, and temporary cross-clamping of the descending aorta to redistribute blood flow to the coronary and cerebral circulations (46). Indications for emergency department thoracotomy in patients with blunt chest trauma are controversial because reported survival rates for both pediatric and adult patients are 0% to 2% with this procedure (47). This is unfortunate, because the vast majority of trauma deaths in the pediatric age group are due to blunt injury.

ELECTRICAL INJURY

The first human fatality caused by alternating current (250 volts) was reported in 1879. Among all age-groups, >1,000 people die each year in the United States because of electrocution on the work site or in the home, and 150 to 300 others die annually from lightning strikes. These deaths are primarily due to fatal cardiac dysrhythmia (48).

Injury from Man-Made Electricity

Ohm's law (amperage = voltage/resistance) describes the inverse relationship between current (A) and tissue resistance (R) and the direct relationship between current (A) and voltage (V). Damage to human tissue from electricity is related to the amount and duration of current that passes through it. In electrical injuries, only voltage is known. The amount of current involved (and resulting tissue damage) is variable, because tissue resistance varies. Overall, bone provides the greatest resistance to current flow, followed in descending order by fat, tendons, skin, muscle, vasculature, and nerves (49). Skin resistance is the most important factor determining the probability of cardiac injury from electrocution. Skin resistance can vary dramatically, depending on skin thickness, vascularity, and, most important, moisture. Although the resistance of dry skin may be 100,000 Ohms, that of moist skin may be as little as 1,000 Ohms. This 100-fold change in skin resistance may mean the difference between a painful electrical shock and the conduction of enough current to cause cardiac dysrhythmia (49).

Alternating current is a greater hazard than direct current. Alternating current can cause tetanic contraction of muscles. Because the forearm flexors are stronger than the extensors, this may prevent the child from being able to let go of an electrical source that he or she has grasped. Additionally,

TABLE 23.4

Factors Affecting Severity of Electrical Injuries

the heart is more sensitive to alternating current than direct current. Cardiac dysrhythmias are more likely to occur from household current at 60 Hz than electrical current of higher frequency. The path of the electrical current through the body also is a determinant of the likelihood of cardiac dysrhythmia. Current passing through the thorax is more likely to cause a dysrhythmia (36). See Table 23.4 for factors influencing electrical injury severity (48).

The mechanism by which electricity injures the heart is unknown. Proposed mechanisms include direct myocardial muscle damage, coronary artery endarteritis, and coronary artery spasm. Myocardial ischemia, resulting from decreased coronary perfusion during electrically induced dysrhythmia, also has been proposed as a mechanism of cardiac damage. The only reported pathologic finding at autopsy is petechial hemorrhages in the myocardium (50). Sudden death owing to low-voltage (110 to 380 V) alternating current found in the household is usually secondary to ventricular fibrillation. Following electrical injury, nonspecific ST-segment and T-wave changes are the most common abnormalities observed on ECG (50).

The use of CPK-MB isoenzyme levels in the diagnosis of myocardial infarction after electrical injury is complicated by the extensive skeletal muscle damage that normally occurs with these injuries. Skeletal muscle damaged by electricity will release large amounts of CPK, including the CPK-MB isoenzyme fraction. Skeletal muscle biopsy adjacent to the site of electrical injury demonstrates an increased production of CPK, as well as increased CPK-MB activity. This increased enzymatic activity is hypothesized to have been stimulated by the electrical injury. The utility of troponin levels in lightning injuries is unknown. The effects of cardiopulmonary resuscitation, as well as direct current countershock during resuscitative attempts, also potentially confuse the picture (50).

Initial emergency management of patients injured by electricity includes attention to the airway, breathing, and circulation and treatment of any cardiac dysrhythmias following pediatric advanced life support (PALS) and advanced cardiac life support (ACLS) protocols. Asymptomatic patients with normal ECGs following electrical injury from low-voltage alternating household current do not require routine cardiac monitoring or admission to the hospital (49,51).

Injury from Lightning

Each second, there are an estimated 100 lightning strikes to the earth's surface worldwide. Lightning is responsible for more deaths in the United States than any other natural disaster. Lightning-related injuries are most common during the

TABLE 23.5 Lightning Versus High-Voltage Electrical Injury

Factor	Lightning	High Voltage
Energy level	30,000,000 V, 50,000 A	Usually much lower
Time of exposure	Brief, instantaneous	Prolonged
Pathway	Flashover orifice	Deep, internal
Burns	Superficial, minor	Deep, major injury
Cardiac	Primary and secondary arrest, asystole	Fibrillation
Renal	Rare myoglobinuria or hemoglobinuria	Myoglobinuric renal failure common
Fasciotomy	Rarely if ever necessary	Common, early, and extensive
Blunt injury	Explosive thunder effect	Falls, being thrown

Adapted from Cooper MA, Andrews CJ, Holle RL, et al. Lightning injuries. In: Auerbach PS, ed. *Wilderness Medicine*. 4th ed. St. Louis, MO: Mosby, 2001.

summer, when there is more thunderstorm activity. Only 20% to 30% of people struck by lightning die, and they are usually the ones who experience immediate cardiopulmonary arrest. However, survivors often suffer from serious sequelae (48).

Lightning-related injuries differ in a number of ways from injuries owing to man-made electricity. Lightning strikes involve brief, massive surges of unidirectional current with an associated shock wave. Current magnitude often exceeds 100,000 A, and >30,000,000 V is seen. The 8,000°C temperature of a lightning stroke is threefold to fourfold higher than that seen with high-voltage man-made current, but contact is extremely brief. Lightning typically flashes over the body, causing only minor or superficial burns. This contrasts with the deep and extensive burns associated with high-voltage alternating current. See Table 23.5 for a comparison of electrical injuries owing to lightning and high-voltage current (48).

The electrical surge associated with a lightning strike is thought to cause widespread myocardial depolarization with subsequent asystole. Ventricular fibrillation also has been commonly reported. Respiratory arrest frequently occurs in lightning strike victims, and the associated hypoxia can prevent cardiac recovery from the initial electrically induced cardiac asystole or other dysrhythmia (48,52).

Myocardial necrosis has been found at autopsy following fatal lightning injury. Myocardial damage may be reflected by ECG abnormalities demonstrating an acute myocardial infarction pattern. Nonspecific ST-T wave changes also have been reported. ECG abnormalities may develop up to several days following the injury (52). Resolution of most ECG changes occurs within a few days, although abnormalities have been reported to last for months (48).

Initial emergency management of children struck by lightning is the same as for those with electrical injuries from man-made sources. Maintenance of a patent airway with adequate oxygenation and ventilation is the highest priority, as well as treatment of cardiac dysrhythmias following PALS and ACLS guidelines (48,52). Any child found with linear or punctate burns, clothes exploded off, tympanic membrane rupture, confusion, outdoor location of discovery, or pathognomonic feathering burns should be managed medically as a lightning strike victim. In the case of multiple casualties in a lightning strike, contrary to standard triage guidelines, resuscitation attempts should be directed first toward those who appear dead. Those who are apneic and asystolic may respond to resuscitative efforts, whereas those with spontaneous respirations are likely to already be recovering (48).

From the Gene to the Neonate

Molecular Determinants of Cardiac Development and Disease

Deepak Srivastava ■ H. Scott Baldwin

The heart has for centuries been the fascination of anatomists, embryologists, biologists, and physicians. As the organ most essential for life, the heart is the first organ to form in an embryo and must function to support the rapidly growing embryo before it has the opportunity to shape itself into a four-chambered organ. The combination of the complex morphogenetic events necessary for cardiogenesis and the superimposed hemodynamic influences may contribute to the exquisite sensitivity of the heart to perturbations. This phenomenon is reflected in the estimated 10% incidence of severe cardiac malformations observed in spontaneously aborted fetuses. The fraction of congenital heart malformations that is hemodynamically compatible with the intrauterine circulation (1% of population) composes the spectrum of congenital heart defects (CHDs), which is the subject of this pediatric cardiology textbook.

These defects affect virtually all of the major structures of the mature heart (Fig. 24.1) (1,2). An additional 1% to 2% of the population harbor more subtle cardiac developmental anomalies that become apparent only as age-dependent phenomena reveal the underlying pathology. With >1 million survivors of CHD in the United States, it is becoming apparent that genetic disruptions that predispose to developmental defects can have ongoing consequences in maintenance of specific cell types and cellular processes over decades (3). A more precise understanding of the causes of CHD is imperative for the recognition and potential intervention of progressive degenerative conditions among survivors of CHD.

The anatomic features of most CHD in humans have been carefully catalogued. Although CHD was classified in the 18th and 19th centuries based on embryologic considerations, the advent of palliative procedures and clinical management led to a descriptive nomenclature founded on anatomic and physiologic features that governed surgical and medical therapy. However, seemingly unrelated CHDs could be argued to share common embryologic origins from a mechanistic standpoint, suggesting that the causes of CHDs may be better understood by considering their developmental bases. Advances in genetics and molecular biology have stimulated a renaissance in seeking an embryologic framework for understanding CHDs

as alterations and null mutations in a wide array of genes have targeted the heart and vascular system and established abnormalities in cardiovascular ontogeny as a primary cause of embryonic demise (4). The ability to go beyond descriptions of the anatomic defects to developing an understanding of the genes responsible for distinct steps of cardiac morphogenesis has raised the prospects that the future of pediatric cardiology will involve more directed therapeutic and preventive measures.

Although human genetic approaches have been important in understanding CHDs, detailed molecular analysis of cardiac development in humans has been difficult. The recognition that cardiac genetic pathways are highly conserved across vastly diverse species from flies to man has resulted in an explosion of information from studies in more tractable and accessible biologic models. The fruit fly (*Drosophila*) has been a source of discovery for genes involved in early cardiac determination events. Although no biologic system is ideal for studying human disease, *Drosophila* has several advantages: It has a simple genome and usually has a single copy of genes that often have three or four homologues in vertebrates; genetic studies are facilitated by the rapid breeding times; and, most important, its DNA can be chemically mutated in a random fashion followed by phenotypic analysis and reverse genetics to identify the DNA mutation associated with distinct developmental defects. Similar chemical mutagenesis efforts have been successful in another model system, the zebrafish. Zebrafish have the added advantages of being vertebrates; having a more complex two-chambered heart; and, because the embryos grow in water, having a heart that is easily visible and not necessary for survival during the period of cardiac development. Although genetic approaches are not feasible in chick embryos, they have four-chambered hearts, and the embryos are easily accessible within the egg for surgical and molecular manipulation during cardiogenesis. Such approaches have been useful in cell fate analyses and defining the role of populations of cells during development. Finally, use of the laboratory mouse, a mammal with a cardiovascular system nearly identical to humans, has been invaluable in understanding the mechanisms underlying human disease. Advances in technology have made it possible to mutate or delete specific genes in the

Figure 24.1. Congenital heart defects. This diagram of the adult heart illustrates the structures that are affected by congenital heart diseases, with the estimated incidence of each disease per 1,000 live births indicated in parentheses. AC, aortic coarctation; AS, aortic stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; BAV, bicuspid aortic valve; DORV, double outlet right ventricle; Ebstein, Ebstein anomaly of the tricuspid valve; HLHS, hypoplastic left heart syndrome; HRHS, hypoplastic right heart syndrome; IAA, interrupted aortic arch; MA, mitral atresia; MS, mitral stenosis; PDA, patent ductus arteriosus; PS, pulmonary artery stenosis; PTA, persistent truncus arteriosus; TA, tricuspid atresia; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect. (From Bruneau BG. The developmental genetics of congenital heart disease. *Nature* 2008, 451:943–948, with permission.)

mouse genome and study the effects of such mutations in mice heterozygous or homozygous for the disrupted gene of interest. Thus, each biologic system offers unique opportunities to develop a deeper understanding of cardiogenesis.

In adults, heart disease is the number one killer of men and women in the United States, with an additional 5 million people surviving with insufficient cardiac function (5). Deciphering nature's secrets of heart formation might lead to novel approaches to repair or regenerate damaged heart muscle. Recent evidence has begun to support this idea and has led to heightened interest in the early events involved in cardiac cell fate decisions and cardiomyocyte differentiation, migration, and survival. The potential of stem cells in regenerative medicine is enormous, and insights into the natural process of cardiogenesis from progenitor cells during embryogenesis will form the basis of reprogramming cells for therapeutic use (4).

In this chapter, anatomic, molecular, and clinical aspects of cardiac embryology are interwoven to develop a framework in which to consider the causes of human CHDs. Clinical lessons combined with experimental studies in mice, fish, and flies have led to a model suggesting that unique regions of the heart have been added in a modular fashion during evolution. In this model, defects in particular regions of the heart would arise from unique genetic and environmental effects during specific developmental windows of time. To simplify the complex events of cardiogenesis, unique regions of the developing heart are considered individually in the context described above. In addition to the classic review of cardiac development by DeHaan (6) in 1965, more recent publications provide additional details into anatomic events that are required for normal cardiac morphogenesis (7–9). The primary focus of this chapter is to highlight recent work that has identified the molecular processes controlling these critical morphologic events.

ORIGIN OF CARDIAC PRECURSORS

Despite decades of cell lineage tracings and descriptive embryology of the heart's origins, only recently has a more complete and accurate picture of cardiogenesis emerged (8). Recent studies, utilizing careful observation of single embryonic stem (ES) cell differentiation, suggest that the primary cell types that comprise the early heart (myocardial, endocardial, and smooth muscle cells) can be derived from a single mesodermal cardiac progenitor (10–13). Two distinct mesodermal heart fields that share a common origin appear to contribute cells to the developing heart in a temporally and spatially specific manner. The well-studied primary heart field is derived from cells in the anterior lateral plate mesoderm that align in a crescent shape at approximately embryonic (E) day 7.5 in the mouse embryo, roughly corresponding to week 2 of human gestation (Fig. 24.2). By mouse E8.0, or 3 weeks in humans, these cells coalesce along the ventral midline to form a primitive heart tube, which consists of an interior layer of endocardial cells and an exterior layer of myocardial cells, separated by extracellular matrix (ECM) necessary for reciprocal signaling between the two layers.

Previous lineage tracings using dye-labeling techniques suggested that cells along the anterior–posterior (AP) axis of the heart tube were destined to contribute to specific chambers of the future heart (14). However, such studies could not determine the clonal contributions of individual cells (15). More recent studies using Cre-lox technologies to mark progenitor cells and all their descendants indicate—in stark contrast to previous models—that the heart tube derived from the primary heart field may predominantly provide a scaffold that enables a second population of cells to migrate and expand into cardiac chambers (8). These additional cells arise from an area often referred to as the

Figure 24.2. Mammalian heart development. Oblique views of whole embryos and frontal views of cardiac precursors during human cardiac development are shown. **A:** First heart field (FHF) cells form a crescent shape in the anterior embryo with second heart field (SHF) cells medial and anterior to the FHF. **B:** SHF cells lie dorsal to the straight heart tube and begin to migrate (arrows) into the anterior and posterior ends of the tube to form the right ventricle (RV), conotruncus (CT), and part of the atria (A). **C:** Following rightward looping of the heart tube, cardiac neural crest (CNC) cells also migrate (arrow) into the outflow tract from the neural folds to septate the outflow tract and pattern the bilaterally symmetric aortic arch arteries (III, IV, and VI). **D:** Septation of the ventricles, atria, and atrioventricular valves (AVV) results in the four-chambered heart. Ao, aorta; AS, aortic sac; DA, ductus arteriosus; LA, left atrium; LCA, left carotid artery; LSCA, left subclavian artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RCA, right carotid artery; RSCA, right subclavian artery; V, ventricle.

secondary heart field (SHF), or anterior heart field, based on its location anterior and medial to the crescent-shaped primary heart field (16–18) (Fig. 24.2). Both heart fields appear to be regulated by complex positive and negative signaling networks involving members of the bone morphogenetic protein (Bmp), sonic hedgehog (Shh), fibroblast growth factor (Fgf), Wnt, and Notch proteins. Such signals often arise from the adjacent endoderm, although the precise nature and role of these signals remain unknown (19–22). SHF cells remain in an undifferentiated progenitor state until incorporation into the heart, and this may in part be due to closer proximity to inhibitory Wnt signals emanating from the midline.

As the heart tube forms, the SHF cells also migrate into the midline and position themselves dorsal to the heart tube in the pharyngeal mesoderm. On rightward looping of the heart tube, SHF cells cross the pharyngeal mesoderm into the anterior and posterior portions, populating a large portion of the outflow tract, future right ventricle, and atria (23) (Fig. 24.2). Precursors of the left ventricle are sparsely populated by the SHF and appear to be derived largely from the primary heart field. In contrast to the primary heart field, SHF cells do not differentiate into cardiac cells until they are positioned within the heart. Once within the heart, primary and secondary heart field cells appear to proliferate in response to endocardial-derived signals such as neuregulin and epicardial signals dependent on retinoic acid, although the mechanisms through which these non-cell-autonomous events occur remain poorly understood (24,25).

TRANSCRIPTIONAL REGULATION OF CARDIAC PRECURSORS

Regulation of the SHF involves numerous signaling and transcriptional cascades (Fig. 24.3). Factors secreted from the anterior portion of the heart tube may serve as chemoattractant signals to induce the migration of SHF cells, although the nature of such molecules remains unknown (18). *Isl1* (*Isl1*), a LIM-domain transcription factor involved in pancreatic development, is necessary for development of the SHF (23). Progeny of *Isl1*⁺ cells contribute to most of the heart except the left ventricle, but *Isl1* expression is extinguished as progenitor cells begin to express markers of cardiac differentiation (24). The mechanisms through which *Isl1* regulates SHF progenitor cells are being explored, with a significant advance coming from the discovery that expression of a forkhead protein essential for SHF development, *Foxh1*, is dependent on *Isl1* (26). *Isl1*⁺ cells also mark niches of undifferentiated cardiac progenitor cells in the postnatal heart (27), suggesting that understanding the regulation of SHF-derived progenitor pools may be useful in developing approaches for cardiac repair (discussed below). Interestingly, common mutations in *Isl1* have been shown to confer genetic susceptibility to CHDs (28).

Discovery of the SHF led to the reinterpretation of findings in mice lacking critical regulatory proteins and in transgenic mice harboring enhancers of genes expressed in the heart. As the molecular aspects of cardiogenesis were first being discovered approximately a decade ago, right ventricle-specific enhancers

the heart appear to be regulated by a muscle-specific member of the SWI/SNF complex, Baf60c (60), suggesting that transcriptional activity of cardiac DNA-binding proteins is highly regulated through epigenetic events.

MicroRNA Regulation of Cardiomyocyte Differentiation

Although transcriptional and epigenetic events regulate many critical cardiac genes, translational control by small noncoding RNAs, such as microRNAs (miRNAs), has recently emerged as another mechanism to fine-tune dosages of key proteins during cardiogenesis (61,62). miRNAs primarily function post-transcriptionally by interacting with the 3' untranslated region (UTR) of specific target mRNAs in a sequence-specific manner (Fig. 24.4). Over 700 miRNAs are encoded in the human genome, and each is thought to target 50 to more than 100 mRNAs, resulting in mRNA degradation or translational inhibition. Interactions between miRNAs and mRNAs are thought to require sequence homology in the 5' end of the miRNA, but significant variance in the degree of complementation in the remaining sequence allows a single miRNA to target a wide range of mRNAs, often regulating multiple genes within a common pathway. miRNAs can often function to influence cell fate decisions including those of the cardiac lineage (63). A common theme has emerged in which miRNAs are often

regulated by the major transcriptional networks controlling cellular decisions and in turn function in positive and negative feedback loops to reinforce and titrate transcriptional decisions through their translational regulation.

Among the first miRNAs to be identified as major regulators of lineage determination were those promoting the formation of muscle (61). Since then, miRNAs have been realized as powerful regulators of cardiac, skeletal, and smooth muscle lineages employing clever regulatory mechanisms impinging on many previously described transcriptional pathways. Two such miRNAs, miR-1 and miR-133, are cotranscribed from a single locus and are uniquely expressed in skeletal and cardiac muscle cells and their progenitors (64,65).

Transcription of the *miR-1/miR-133* bicistronic precursors is directly regulated by the major myogenic differentiation factors, MyoD, myocyte enhancer factor-2 (Mef2), and serum response factor (SRF), early expressed in the muscle mesoderm (61). The influence of miR-1 in promoting the muscle identity is so strong that misexpression of this single miRNA in fibroblasts is sufficient to largely transform their gene program to that of muscle cells (66). Indeed, miR-1 can promote the differentiation of skeletal muscle from myoblast precursors, in part by targeting a repressor of the muscle master regulator Mef2c, which further drives expression of miR-1 (64). Deletion of miR-1 in flies results in a defect in somatic and cardiac muscle differentiation (62,67), where miR-1 regulates Notch signaling and cell polarity (68).

Figure 24.4. Current model of miRNA biogenesis and function. The initial RNA is transcribed by RNA polymerase II as primary miRNAs (pri-miRNAs). These pri-miRNAs range from a few hundred to thousands of nucleotides (nt) in length. The pri-miRNA of each miRNA has a characteristic stem-loop structure that is detected and cleaved by the ribonuclease III (RNase III) endonuclease Drosha within the nucleus. Efficient pri-miRNA cleavage by Drosha requires a protein partner, Pasha/DGCR8, which has a double-stranded RNA-binding domain (dsRBD). The cleavage product, approximately a 70-nt stem-loop RNA called pre-miRNA, is exported from the nucleus to the cytoplasm by Exportin 5/RanGTP. In the cytoplasm, another evolutionarily conserved RNase III enzyme, Dicer, together with its dsRBD protein partner, TRBP and PACT, further process pre-miRNA into mature miRNA approximately 21 nt in length. The mature miRNA is then unwound and a single strand is incorporated into a protein complex known as the RNA-induced silencing complex (RISC), which represses mRNA translation or destabilizes mRNA transcripts through cleavage or deadenylation.

During early cell fate decisions of mouse and human ES cells, *miR-1* and *miR-133* function in concert to promote mesoderm induction, while suppressing differentiation into the ectodermal or endodermal lineages (69). However, *miR-1* and *miR-133* have antagonistic effects on further adoption of muscle lineages: *miR-1* promotes differentiation of mouse and human ES cells toward a cardiac fate, while *miR-133* inhibits differentiation into cardiac muscle. *miR-1* appears to exert this effect, in part, by translationally repressing the mammalian orthologue of *delta*, *Delta-like-1* (*Dll-1*), similar to the repression seen in the fly (69). Thus, the bicistronic *miR-1/miR-133* transcript encodes distinct mature miRNAs that likely share common targets yet complement each other by balancing the differentiation and proliferation of cardiac and skeletal muscle lineages. Interestingly, loss of two alleles of *miR-133* or one allele of *miR-1* causes similar ventricular septal defects (VSDs), consistent with them sharing some common targets (65,70).

Mir208a, contained within the introns of *Myh6* and *Myh7* and highly enriched in embryonic heart, targets *GATA4* and plays a fine tuning role in early cardiac development, although its deletion did not reveal any embryonic cardiac phenotype (71). Wilson et al. (72) reported a cardiac “miRNA-ome,” a miR profile of early cardiomyocytes derived from human ES cells. They found *miR1*, *133* and *208* confirming miRs share their function in mouse embryos and differentiating human ES cells. They further revealed *miR-499* as an upstream regulator of *Mef2c* expression.

Another cotranscribed pair of miRNAs expressed early during cardiogenesis under control of *SRF* and that play a key role in cell fate decision is *miR-143* and *miR-145* (69,73). These two miRNAs are down-regulated during cardiogenesis but are critical regulators of smooth muscle cells, which uniquely oscillate between proliferative or more quiescent, differentiated states. The cotranscribed *miR-143* and *miR-145* cooperatively target a network of transcription factors, including *Klf4* and *Elk-1*, to promote differentiation and repress proliferation of smooth muscle cells in vitro (73). Given their intercalation into these major regulatory pathways, their ability to direct differentiation of multipotent progenitors was also investigated. Indeed, *miR-145* had the unique capacity to induce smooth muscle gene expression and synergize with the smooth muscle master regulator, *Myocardin*. In addition, *miR-145* was able to potently and rapidly direct the differentiation of multipotent neural crest stem cells into smooth muscle (73). Although *miR-145* was not required for smooth muscle differentiation in vivo or in vitro, loss of *miR-145* resulted in a more proliferative, less differentiated state of smooth muscle in vivo (74).

Complex Regulation of Cardiac Morphogenesis

Although the pathways regulating individual cell lineages contributing to the heart are deeply understood, the subsequent complex events involved in integrating multiple cell types, formation of chambers, and patterning of the distinct regions of the heart are also now being elucidated. Major components involving the sequential development of the mouse heart, the primary genetic model for the study of cardiac morphogenesis, have recently been extensively reviewed (75). From an evolutionary standpoint, it appears that as organisms became more complex, a more elaborate cardiovascular system was required. Distinct cardiac chambers began to develop and adopted specialized functions. Fish, which have a circulatory system that functions in series, developed separate atrial and ventricular chambers with a single inflow and outflow tract. The single ventricle pumps blood to the body via the gills, and no separation of deoxygenated and oxygenated blood is necessary. The amphibious frog adopted an intermediate three-chambered heart. In contrast, terrestrial vertebrates required complete separation of oxygenated and deoxygenated blood after birth, necessitating

two separate atrial and ventricular chambers along with two distinct inflow and outflow tracts. These evolutionary observations suggest that the heart was built in modules that were added as they became necessary. The discovery of distinct heart fields as described above and evidence of modular gene expression in the heart supports such a notion.

Dorsal–Ventral Polarity

Beyond the asymmetric addition of SHF cells along the AP axis, a discrete dorsal–ventral (DV) polarity occurs in the primitive heart tube. As the heart tube loops to the right, the ventral surface of the tube rotates to become the outer curvature of the looped heart, and the dorsal surface forms the inner curvature. The outer curvature becomes the site of active growth, whereas remodeling of the inner curvature is essential for the ultimate alignment of the inflow and outflow tracts of the heart. A model in which individual chambers “balloon” from the outer curvature in a segmental fashion has been proposed (76). Consistent with this model, numerous genes, including the transcription factor *Hand1* and the sarcomeric protein *Serca2*, are expressed specifically on the outer curvature of the heart (47,77). *Hand2* is expressed on the inner and outer curvature, but protein production of *Hand2* in the inner curvature may be repressed by miRNA regulation, as *miR-1* is first detected in the inner but not outer curvature at E8.5 (61). Also, through a complex transcriptional network, the unique identity of inner curvature cells is determined by *Tbx2*-mediated repression of genes typically found on the outer curvature (78). Another *Tbox* transcription factor, *Tbx20*, serves to repress *Tbx2* activity in the outer curvature as it expands into the cardiac chambers, thereby establishing the regional patterning of expanding or remodeling myocardium (79–81). Remodeling of the inner curvature allows migration of the inflow tract to the right and the outflow tract to the left, facilitating proper alignment and separation of right- and left-sided circulations. In addition to its role in repressing *Tbx2*, *Tbx20* affects expansion of both the primary and secondary heart field-derived cells and is necessary for outflow tract development, possibly via regulation of *Nkx2.5* and *Mef2c* (79).

Left–Right Asymmetry and Cardiac Looping

Rightward looping of the heart tube with the caudal portion of the tube moving to a more anterior and dorsal position is the first obvious sign of the break in left–right (LR) symmetry. The cellular mechanisms that drive cardiac looping remain poorly understood, but it has been postulated that differential rates of proliferation of cardioblasts, regional differences in intracardiac actin bundles, or altered cell adhesion across the heart tube may be involved. When considering the mechanisms for cardiac looping, it is important to distinguish between the process of looping and the directionality of looping (82). Directionality of looping reflects overall asymmetry throughout the embryo, which is superimposed on the morphogenetic mechanisms for looping.

It has been proposed that abnormalities in the process of cardiac looping underlie a number of CHDs. Folding of the heart tube positions the inflow cushions adjacent to the outflow cushions and involves extensive remodeling of the inner curvature of the looped heart tube. In the primitive looped heart, the segments of the heart are still in a linear pattern and must be repositioned considerably for alignment of the atrial chambers with the appropriate ventricles and the ventricles with the aorta and pulmonary arteries. The atrioventricular septum (AVS) begins to divide the common atrioventricular canal (AVC) into a right and left AVC that subsequently shifts to the right to position the AVS over the ventricular septum (Fig. 24.5). This allows the right AVC and the left AVC to be aligned with the right and left ventricles, respectively. Simultaneously, the conotruncal region becomes septated into the aorta and pulmonary trunks as the conotruncus moves

Figure 24.5. Normal and abnormal cardiac morphogenesis associated with LR signaling. **A:** As the linear heart tube loops rightward with inner curvature (ic) remodeling and outer curvature (oc) proliferation, the endocardial cushions (dark blue) of the inflow (green) and outflow (light blue) tracts become adjacent to one another. Subsequently, the AVS shifts to the right, while the aortopulmonary trunk shifts to the left. **B:** The inflow tract is divided into the right (ravc) and left atrioventricular canal (lavc) by the AVS (asterisk). The outflow tract, known as the truncus arteriosus (ta), becomes the aortopulmonary trunk (apt) on septation. **C:** Ultimately, the left (la) and right atrium (ra) are aligned with the left ventricle (lv) and right ventricle (rv), respectively. The lv and rv become aligned with the aorta (ao) and pulmonary artery (pa), respectively, after 180-degree rotation of the great vessels. **D:** If the determinants of the LR axis are coordinately reversed, then a condition known as situs inversus results. **E:** If the apt fails to shift to the left, then a condition known as double-outlet right ventricle (DORV) results, in which the RV is aligned with both the aorta and pulmonary artery. **F:** Likewise, if the AVS fails to shift to the right, both atria communicate with the left ventricle in a condition known as double-inlet left ventricle (DILV). **G:** Transposition of the great arteries (TGA) results if the apt fails to twist, resulting in communication of the rv with ao and lv with pa. av, aortic valve; mv, mitral valve; pv, pulmonary valve; vsd, ventricular septal defect.

toward the left side of the heart such that the conotruncal septum is positioned over the AVS (Fig. 24.5). The rightward shift of the AVS and leftward shift of the conotruncus converts the single-inlet, single-outlet heart into a four-chambered heart that has separate atrial inlets and ventricular outlets (83).

Arrest or incomplete movement of the AVS or conotruncus might result in malalignment of the inflow and outflow tracts (Fig. 24.5). A scenario in which the AVS fails to shift to the right would result in communication of the right and left AVCs with the left ventricle, a condition known as double-inlet left ventricle (DILV). Incomplete shifting may be the basis for “unbalanced” AVC defects where the right AVC only partly communicates with the right ventricle. Similarly, if the conotruncal septum fails to shift to the left, both the aorta and pulmonary artery would arise from the RV causing a double-outlet right ventricle (DORV). From this embryologic perspective, it is not surprising that double-outlet left ventricles and double-inlet right ventricles are rarely, if ever, seen

clinically. In contrast, any abnormality in cardiac looping can be associated with DILV or DORV, along with other manifestations of improper alignment of specific regions of the heart.

The elegant molecular network regulating LR asymmetry of the body plan has been reviewed (84) and is not summarized here. However, it is worth highlighting several clues about the relationship between LR asymmetry and proper alignment of the cardiac chambers. The cascade of LR signals including *Shh* and *Nodal* converge on the transcription factor *Pitx2* (85). *Pitx2* is initially LR asymmetric in the linear heart tube, but this asymmetry is translated into a DV polarity in the looped heart tube. Because *Pitx2* regulates cell proliferation via cyclin D2 and also controls cell migration events (86), it is a potential link between signals regulating the direction and process of cardiac looping. Within certain subdomains, regulation of *Pitx2* by *Tbx1* integrates transcriptional pathways controlling morphogenesis and LR asymmetry (87).

How do the insights into LR asymmetry impact our understanding of CHDs? It is likely that patients with situs inversus totalis have a well-coordinated reversal of LR asymmetry and thus have a lower incidence of defects in visceral organogenesis. However, most patients with LR defects have viscerotaxial heterotaxy and thus have randomization of cardiac, pulmonary, and gastrointestinal situs where coordinated signaling is absent. Such patients can have defects in almost all aspects of cardiogenesis. Often either the right or left side predominates with patients either having bilateral right-sidedness (asplenia syndrome) or bilateral left-sidedness (polysplenia syndrome). In such cases, features of the right or left side of the lungs, heart, and gut are duplicated. Disruption of cascades determining either the left or right side of the embryo might result in asplenia or polysplenia syndromes, respectively. Indeed, mutations in LR pathway members are found in some patients with heterotaxy (88). Familial cases of heterotaxy have also led to identification of mutations in a zinc-finger transcription factor, *ZIC3*, that result in LR axis abnormalities (89).

Cardiac Outflow Tract Regulation

Congenital cardiac defects involving the cardiac outflow tract, aortic arch, ductus arteriosus, and proximal pulmonary arteries account for 20% to 30% of all CHDs. This region of the heart undergoes extensive and rather complex morphogenetic changes with contributions from neural crest cells and the SHF, as discussed above. The cardiac outflow tract can be divided into the muscularized conus and the adjacent truncus arteriosus, collectively termed the conotruncus, as it arises from the primitive right ventricle. The conotruncus normally shifts to the left to override the forming ventricular septum. The truncus arteriosus then becomes septated by mesenchymal cells into the aorta and pulmonary arteries with a muscular ridge forming between the two vessels known as the conotruncal septum (Fig. 24.5). However, at this stage, the aorta communicates with the RV and the pulmonary artery with the left ventricle. Subsequent rotation of the two vessels in a spiraling fashion places the aorta in a more dorsal and leftward position and the pulmonary artery in a more ventral and rightward location. This spiraling event achieves the normal alignment of the aorta and pulmonary artery to the left and right ventricles, respectively.

Abnormalities in septation or incomplete spiraling of the conotruncus result in many CHDs. For example, the

conotruncal septum between the aorta and pulmonary artery forms in tetralogy of Fallot (TOF), but because of malalignment of the great vessels, the conotruncal septum and aorta are shifted to the right. This results in an overriding aorta and failure of the conotruncal septum to connect to the muscular ventricular septum, resulting in a VSD (Fig. 24.5). Similarly, any malalignment of the conotruncus results in an obligatory VSD that, unlike muscular VSDs, does not have the potential to close spontaneously after birth.

A structure referred to as the aortic sac lies distal to the conotruncus and gives rise to six bilaterally symmetric vessels known as aortic arch arteries. The aortic arch arteries arise sequentially along the AP axis, each traversing a pharyngeal arch before joining the paired dorsal aortae (Fig. 24.6). The first and second arch arteries involute, and the fifth arch artery never fully forms. The third, fourth, and sixth arch arteries undergo extensive remodeling to ultimately form distinct regions of the mature aortic arch and proximal pulmonary arteries. Most of the right-sided dorsal aorta and aortic arch arteries undergo programmed cell death leading to a left-sided aortic arch. The third aortic arch artery contributes to the proximal carotid arteries and right subclavian artery (RSCA). The left fourth aortic arch artery forms the transverse aortic arch between the left common carotid (LCC) and left subclavian arteries. Finally, the sixth arch artery contributes to the proximal pulmonary artery and the ductus arteriosus (90). Extrapolating from their embryologic origins, it is believed that aberrant right subclavian arteries and other subtle arch anomalies are the result of third aortic arch defects; interrupted aortic arch (IAA) from fourth arch defects; and patent ductus arteriosus (PDA) and proximal pulmonary artery hypoplasia/discontinuity from defects in sixth arch artery development.

Mesenchyme cells originating from the crest of the neural folds are essential for proper septation and remodeling of the outflow tract and aortic arch (91,196,197). Such neural crest-derived cells migrate away from the neural folds and retain the ability to differentiate into multiple cell types (Fig. 24.6). The migratory path and ultimate fate of these cells depends on their relative position of origin along the AP axis and are partly regulated by the Hox code (92). Neural crest cells differentiate and contribute to diverse embryonic structures, including the cranial ganglia, peripheral nervous system, adrenal glands, and melanocytes. Neural crest cells that arise from the otic placode to the third somite migrate through the developing pharyngeal

Figure 24.6. Cardiac neural crest contributions to aortic arch development. Cardiac neural crest cells arise from the neural folds and migrate into the outflow tract of the heart and aortic arch arteries. They are involved in remodeling the arch arteries, with derivatives color coded by their arch artery origins. arches and populate the mesenchyme of each of the aortic arch arteries and the mesenchyme necessary to septate the outflow tract septum (Fig. 24.6). Because of their migratory path and role, this segment of the neural crest is often referred to as the cardiac neural crest (CNC).

Mutations in many signaling cascades affect neural crest migration or development, including the endothelin and semaphorin pathways, and cause outflow tract defects similar to those observed in humans (91). Embryos deficient in CNC cell migration or differentiation display various cardiac outflow tract and aortic arch defects resembling those in humans. These include TOF, persistent truncus arteriosus (PTA), DORV, VSDs, and defects of aortic arch patterning. Thus, abnormalities in neural crest migration or differentiation likely underlie many of the conotruncal and aortic arch defects seen in humans. Indeed, human mutations of the neural crest-enriched transcription factor *TFAP2 β* result in persistent patency of the ductus arteriosus, a specialized aortic arch vessel essential for fetal cardiac physiology (93) (Fig. 24.6). It is likely that other genetic mutations affect specific regions of the aortic arch.

Disruption of SHF development by mutation of genes such as *Tbx1*, *Fgf8*, and *Isl1* results in defects similar to those observed with neural crest disruption (Fig. 24.3), including PTA (failure of outflow septation), malalignment of the outflow tract of the heart with the ventricular chambers, and VSDs (21,38,44,45). Since SHF-derived myocardial cells neighbor neural crest-derived cells and secrete growth factors such as *Fgf8* in a *Tbx1*-dependent manner that influence neural crest cells (39), reciprocal interactions between the SHF and neural crest-derived cells in the outflow tract are likely essential for normal development. Consistent with this, humans with deletion or mutation of *TBX1* (94), expressed in the SHF, appear to have cell-autonomous defects of SHF development and non-cell-autonomous anomalies of neural crest-derived tissues. It will be interesting to determine if many human cardiac outflow tract defects are a direct result of SHF migration, differentiation, or proliferation.

Cardiac Valve Formation

Critical events regulating cardiac valve development have been recently reviewed (95,96). Appropriate placement and function of cardiac valves is essential for chamber septation and for unidirectional flow of blood through the heart. A molecular network involving *Bmp2* and *Tbx2* defines the position of the valves relative to the chambers (78,97,98). During early heart tube formation, “cushions” of ECM between the endocardium and myocardium presage valve formation at each end of the heart tube. Reciprocal signaling, mediated in part by TGF- β family members, between the myocardium and endocardium in the cushion region induces a transformation of endocardial cells into mesenchymal cells that migrate into the ECM cushion (99–101). These mesenchymal cells differentiate into the fibrous tissue of the valves and are involved in septation of the common AVC into right- and left-sided orifices (102).

Although the processes regulating early epithelial to mesenchymal transition (EMT) in the AVC have been extensively investigated as described above, our understanding of the mechanisms regulating later stages of semilunar valve development are still primarily limited to morphogenic descriptions. This is due, in part, to the fact that this period of development has been essentially inaccessible to experimental manipulation because gene perturbation studies result in embryonic demise in the midgestation mouse embryo. However, based on studies of normal mouse and human embryos (103,104), investigators have demonstrated that the endocardial cushions form condensed mesenchymal protrusions, the primitive valves. These condensed mesenchymal protrusions subsequently elongate to provide the true cardiac valve leaflets (Fig. 24.7). The elongation of primitive valves appears to be a result of restricted proliferation of endocardial cells overlying the mesenchymal projections on the vascular side of the valve and selective cell death under the expanding endocardial rim. The growth of the endocardial edge and evacuation of apoptotic cells underneath the proliferating endocardial rim sculpt the swollen mesenchymal primitive valves into a typical excavated shape and result in morphogenesis of the sinuses of Valsalva.

Figure 24.7. Summary of the critical stages in semilunar valve formation. Initially, regional swellings of ECM form the endocardial cushions, which provide valve-like action ensuring that initial blood flow is unidirectional in the developing embryo. Subsequently, endothelial cells undergo a mesenchymal transformation and populate the endocardial cushions. Finally, the endothelial cells on the arterial face proliferate and the ECM is remodeled to begin valve cusp histogenesis. Subsequently, a selected population of mesenchymal cells is thought to undergo apoptosis simultaneously with continued remodeling of the ECM to form the sinuses, which will eventually become the origin of the proximal coronary arteries. The *black arrows* denote the direction of blood flow. (Figure courtesy of Dr. Peggi Angel.)

Recent studies using immunohistochemistry and electron microscopy described late gestational and postnatal valve development in chicken and mouse (105), with a remarkably similar progression of developmental events seen in human fetuses (106) (Fig. 24.8). These studies document progression of remodeling and compartmentalization of the valve leaflet from a disorganized matrix of proteoglycans with little detectable elastin, and small amounts of disorganized collagen and relative uniform distribution of vascular interstitial cells (VICs), to a highly stratified ECM. The ECM contains three organized layers of fibrosa (arterial aspect primarily composed of collagens), spongiosa (central aspect, primarily glycosaminoglycans), and ventricularis (ventricular aspect with elastin fibers) with compartmentalization of VICs resulting in increased cell density in the fibrosa and ventricularis. Notably, this process is not only conserved across species but extends well after birth into postnatal life. Interestingly, the fetal VIC activation that occurs throughout development is similar to the valve changes occurring in pathologic conditions (107,108), suggesting that analogous molecular mechanisms likely direct both normal developmental and pathologic interstitial cell activation (101). Furthermore, recent experiments have suggested that a small population of VICs may reside as a progenitor cell population that retains the ability to differentiate into either endothelial or interstitial cells in the valve leaflet (109).

A few mouse mutants escape early embryonic demise and are thus informative in unraveling the mechanisms of late gestational and early postnatal semilunar valve pathology. Most of these mouse models display normal EMT but then evolve a

hyperplastic valve phenotype that suggests aberrations in valve remodeling. One common feature of many of these defects is perturbations that either enhance or attenuate RAS-MAPK signaling (110,111). Gitler et al. (112) showed that hyperplastic aortic valve defects in neurofibromatosis 1 (NF1) mutant embryos, previously attributed to defects in CNC cells, result from a primary defect in outflow tract and AVC endocardium. These defects were at least partially due to elevations in endocardial MAPK signaling secondary to the loss of NF1 suppression of *Ras-Erk* signaling, resulting in increased proliferation and decreased apoptosis (113). Consistent with this, patients with NF1 mutations develop pulmonary stenosis and hypertension but rarely defects in the AVC (114). NF1 loss of function is mimicked by gain-of-function mutations in the tyrosine phosphatase *Shp2/PTPN11*, which causes an increase in *Ras-Erk* activation, increased proliferation, and decreased apoptosis, resulting in semilunar valve and atrioventricular valve (AVV) hyperplasia (115,116). Autosomal dominant gain-of-function mutations in *Shp2* cause Noonan syndrome, characterized by pulmonary stenosis, hypertrophic cardiomyopathy, and occasional AVV defects (117,118). Most recently, hypomorphic mutations in *SOS1*, an essential RAS guanine nucleotide-exchange factor (*Ras-Gef*), result in enhanced RAS-ERK activation and can account for as many as 20% of the cases of Noonan syndrome not explained by *Shp2* mutations (119,120).

Recent evidence implicates EGF signaling as an important regulator of late valve remodeling. Loss or attenuation of EGFR/Erbb1 signaling results in preferential hypercellularity of semilunar

Figure 24.8. A: ECM composition of human cardiac valves from fetus to adult. At 14 to 19 weeks (Top, Movat pentachrome; bottom, picrosirius red under circularpolarized light). Fetal valves were composed mostly of glycosaminoglycans with low elastin and collagen. A trilaminar structure was apparent in children's valves but remained diffuse when compared with normal adult valve collagen in the fibrosa, glycosaminoglycans in the spongiosa, and elastin in the ventricularis. B: Progressive decrease in VIC density throughout life. C: Nuclei staining positively for Ki-67 (MIB-1) to detect proliferation were distributed diffusely through the cusp at 14 to 19 weeks of gestation, whereas Ki-67 and TUNEL-positive cells (marking apoptosis) at 20 to 39 weeks appeared predominantly near the arterial surface. VICs in adult valves showed undetectable levels of proliferating and apoptotic cells. D: Fetal valves at 14 to 19 weeks of gestation had higher VIC proliferation indices, with 90% reduction in adult valves. Apoptosis continued at a low rate throughout life. (Adapted from Aikawa E, Whittaker P, Farber M, et al. Human semilunar cardiac valve remodeling by activated cells from fetus to adult: implications for postnatal adaptation, pathology, and tissue engineering. *Circulation* 2006;113:1344-1352, with permission.)

but not AV valves (121). The hyperplastic semilunar valve phenotype is augmented when crossed to mice heterozygous for a null mutation in *Shp2* (122). Deletion of the EGF ligand, heparin binding (HB)-EGF, results in increased endocardial cushion size and cell proliferation of both semilunar and AV valves (123,124). These mice show prolonged Smad 1/5/8 phosphorylation and loss of phospholipase E (125), a downstream component of EGF and Ras signaling, and are similar to mice with a null mutation in inhibitory Smad6 (126). In contrast, mice lacking the Erb3 receptor die in midgestation of heart failure from hypoplastic semilunar and AV valve primordia (127). Null mutations in other EGFR ligands (EGF, amphiregulin, TGF- α) have no effect on valve formation. Finally, mice lacking Ephrin B2 also have thickened valves, and although the mechanism for this remains unclear, it will be interesting to determine how these signaling pathways intersect (128). The exact mechanism of regulation is likely to be context dependent and receptor specific and may involve the intersection of multiple growth factor signaling pathways.

In contrast to the thickened leaflets described above, disruption of signaling pathways converging on the transcription factor *Nfatc* revealed a requirement of this calcium-activated regulator. *Nfatc* is expressed specifically in the forming embryonic valves, and targeted deletion of *Nfatc* in mice results in absence of cardiac valve formation (129,130). Signaling via the phosphatase, calcineurin, results in nuclear translocation of *Nfatc* and is similarly involved in cardiac valve formation, in part through regulation of vascular endothelial growth factor (Vegf) expression in the endocardium (131).

The Notch signaling pathway is required for cell fate and differentiation decisions throughout the embryo (132), but

only recently have Notch proteins been implicated in vertebrate cardiac development. In fish and frogs, Notch appears to be involved in development of the endocardial cushions that contribute to valve tissue (133). In humans, heterozygous *NOTCH1* mutations disrupt normal development of the aortic valve and occasionally the mitral valve (134) (Fig. 24.9). The severity of valve disease associated with *NOTCH1* mutations in humans varies widely from mild disease in which the aortic valve has two rather than three leaflets (bicuspid aortic valve [BAV]) to severe defects in valve patency in utero, resulting in left ventricular growth failure. Consistent with this genetic finding, 15% of “normal” relatives of children with hypoplastic left heart syndrome (HLHS) have subclinical bicuspid aortic valves (BAVs) (135,136), suggesting that disruption of the NOTCH signaling cascade may underlie a spectrum of aortic valve disease. Although not specifically affecting valves, human mutations in *JAGGED1*, a NOTCH ligand, also cause outflow tract defects associated with the autosomal dominant disease, Alagille syndrome (127–139). The hairy-related family of transcriptional repressors (*Hrt1*, *Hrt2*, and *Hrt3*) may mediate the Notch signal during valve and myocardial development; however, their targets for repression remain unknown (140) (141).

GENETICS OF HUMAN SEPTAL DEFECTS

There has been an explosion in the identification of candidate genes potentially involved in the etiology of CHD and role of these genes impacts virtually every aspect of early cardiac development

Figure 24.9. Origin and genetic etiology of congenital heart disease. Three major classes of developmental defects are indicated: defects in atrial septation, in ventricular or atrioventricular septation, and in the great vessels. The types of congenital heart disease that occur within each class are indicated, with the associated mutated genes listed. Genes for which mutations result in discrete congenital heart diseases are indicated in *black*; genes that are mutated in congenital heart diseases that are part of a wider syndrome (also involving defects that are not associated with congenital heart disease) are indicated in *blue*. *CRELD1*, cysteine-rich with epidermal growth-factor-like domains 1; *KRAS*, ki-Ras; *PTPN11*, protein tyrosine phosphatase, nonreceptor type 11; *SOS1*, son of sevenless homologue 1. summarized in Figure 24.9. This has been extensively reviewed elsewhere (2,142–144) and in other chapters of this book. However, we would like to focus on the cardiac transcription factors NKX2.5, TBX5, and GATA4 as they particularly exemplify the synergy between human genetics and studies of model organisms for understanding the etiologic factors of human CHD. Numerous point mutations have been identified in NKX2.5 in families with atrial septal defects (ASDs) and progressive cardiac conduction abnormalities (145). Retrospective analysis of mice heterozygous for *Nkx2.5* disruption revealed a similar phenotype and progressive apoptotic loss of conduction cells, suggesting a likely mechanism for the human phenotype (146,147).

Humans with Holt–Oram syndrome, caused by mutations in *TBX5*, have cardiac anomalies similar to those with NKX2.5 mutations (atrial and ventricular septal defects) as well as limb abnormalities (148,149). Intriguingly, mutations responsible for defects in the heart and limbs are clustered in different regions of the protein, suggesting that TBX5 engages different downstream genes or cofactors in these tissues that depend on unique structural motifs in the protein. One potential cofactor is NKX2-5, as the two physically interact and cooperate to activate common target genes (150).

Like the NKX2.5 and TBX5 mutations, mutations in the zinc-finger-containing protein GATA4 cause similar atrial and ventricular septal defects in autosomal dominant nonsyndromic human pedigrees (151). GATA4 or related proteins are essential for cardiogenesis in flies, fish, and mice (152–155). Like NKX2.5, GATA4 and TBX5 also form a complex to regulate downstream genes, such as myosin heavy chain. Consistent with an important role for such combinatorial interactions, a familial GATA4 point mutation disrupts GATA4's ability to interact with TBX5 (134). Conversely, several human TBX5 mutations disrupt TBX5 interaction with GATA4, suggesting that the two cooperate in cardiac septation events (151). GATA4, TBX5, and NKX2-5 may form a common complex that is necessary for proper cardiac septation (Fig. 24.3). Disruption of any one of the three proteins or their interactions can result in atrial or ventricular septal defects. Although the compendium of septal genes regulated by these transcription factors is unknown, it is intriguing that mutations in human myosin heavy chain (MHC), a direct target of GATA4, TBX5, and NKX2-5, also cause ASDs (156). This observation suggests a possible mechanism by which these genes cause septation defects.

THE EPICARDIUM, CORONARY VASCULARIZATION

The origin of coronary vascular endothelium and formation of the coronary vessels has been an area of intense investigation (157). Several theories have evolved to explain coronary morphogenesis, which range from the sprouting of vessels from the aorta into developing myocardium to outgrowth of the endocardial lining of the heart to the epicardial vessels. Such theories have evolved from descriptive examination of the coronary ontogeny of various animals as well as human embryos. A critical component from most of these reports was the observation that coronary vessel formation was coordinately related to epicardial formation.

Several investigators have demonstrated that the epicardium originates as a villous projection of mesothelial cells in the area of the sinus venosus termed the proepicardial organ. This cluster of cells extends to the AV region and migrates out over the myocardial surface to completely encase the heart (158–162). In vitro data initially suggested that this villous or mesothelial projection might be one possible source of the coronary arteries (163). The correlation between epicardial formation and coronary ontogeny has been clarified in three series of experiments. Using retroviral

tagging of cells initially infected while in the pre-epicardial mesothelium, Mikawa and Fischman (164) were able to document that coronary smooth muscle cells, perivascular fibroblasts, and coronary endothelial cells all derive from independent precursors that arise outside the heart and that the endothelium of the coronary arteries and endocardium have different clonal origins. In complementary experiments, Poelmann et al. (165) used quail epicardial and liver tissue transplanted into chicken so that endothelial cells of quail origin could be identified. These experiments demonstrated that the entire coronary endothelial vasculature originated from an extracardiac source. In addition, this approach suggested that endothelial cells originating from the liver mesenchyme and located within this mesothelial projection or epicardial primordium used the subepicardial matrix to completely vascularize the developing heart. This subepicardial matrix is rich in fibronectin and vitronectin, a conducive ECM for vascular development E104–15. In a definitive set of experiments using retroviral injections directly into the proepicardial organ as well as proepicardial transplants, Mikawa and Gourdie (166) were able to demonstrate that this cluster of extracardiac cells contained differentiated endothelial cells, smooth muscles, and perivascular cells that would ultimately serve as the source of precursors for the coronary vascular bed. These experiments were later confirmed and expanded using a novel in vitro assay of epicardial differentiation (167). All of these experiments provide compelling evidence that coronary artery formation appears to be primarily a vasculogenic process. The coronary angioblasts originate from precursors located within the extracardiac pre-epicardial mesothelium and subsequently organize within the subepicardial matrix into the coronary vascular network. Recently, Red Horse et al. (168) used Cre-lox lineage tracing to confirm that in the mouse, another major contribution of coronary endothelial cells is derived from venous endothelial cells that enter the heart via sinus venosus/SHF and are subsequently reprogrammed to become arterial endothelial cells.

Interestingly, the epicardium is important not only for early developmental cardiac events, but plays a pivotal role in modulating cardiac repair after myocardial injury. Zhou (169) et al. recently demonstrated that while epicardial cells are normally quiescent in the adult, they become “activated” following myocardial injury. Activated epicardial cells undergo proliferation and undergo EMT, forming a layer of cells in the subepicardium that express smooth muscle cell and fibroblast markers and most importantly, secrete angiogenic factors that attenuate infarct size and improve heart function.

Whereas distal coronary development occurs by vasculogenesis, proximal coronary artery morphogenesis appears to result from an angiogenic process. Although traditionally the proximal coronary arteries were described as an outgrowth from the aorta to the epicardial surface of the heart, several investigators have recently shown that in fact the angiogenic process is in the reverse direction. Angiogenic sprouts from the subepicardial endothelial plexus form endothelial strands that grow into the aorta and develop multiple communications with all three cusps of the developing aortic valve (170–172). However, lumens develop only in facing semilunar sinuses with resorption of the strands to the nonfacing or noncoronary cusp (165). These observations have obvious implications for determining the factors that direct coronary artery anatomy in CHDs.

CONDUCTION SYSTEM MORPHOGENESIS

Despite the centrality of electrophysiologic abnormalities to CHDs, very little is known about development of the cardiac conduction system though significant progress has been made recently utilizing both chicken and mouse models (173). A central controversy has revolved around whether primary

conduction tissue differentiates from contractile myocytes or whether it is derived from “invading” neural crest. Using retroviral lineage tracing similar to that described above for defining the source of the coronary vasculature, Gourdie et al. (174) were able to show that pulse-generating conduction cells were derived from local recruitment of differentiated myocytes along the developing coronary artery system. This same group has gone on to demonstrate that endothelin produced by the developing coronary vasculature is a primary mediator of this recruitment of myocytes to the conduction lineage (175). Thus, initial development of the distal conduction system is independent of neural crest. However, the neural crest cells may exert a later, indirect effect on conduction system development via their role in maintaining the coronary vasculature (176,177). Establishment of epicardial to endocardial gradients of key channels is also important for appropriate depolarization and is in part regulated by the transcription factor *Irx5* (178). Networks of transcription factors involving *Nkx*, *T-box*, and *Irx* family members appear to control discrete aspects of the cardiac conduction system and are disrupted in human arrhythmias (55,179). These observations pave the way for a more detailed evaluation of the factors that regulate normal and potentially abnormal development of the conduction system.

ADULT CONSEQUENCES OF CARDIAC MALFORMATIONS

As human survivors of cardiac malformations ranging from simple ASDs to more complex heart disease enter their third and fourth decades of life, new cardiac disease processes are becoming apparent, including abnormal conduction of electricity within the heart and diminished contractile function of the heart. The cause of these secondary defects had in the past been ascribed to abnormal hemodynamics, but recent evidence suggests that the same genes that cause early morphologic defects in heart development might later be directly involved in cardiac dysfunction and cell lineage disturbances in adulthood (3).

For example, human and mouse mutations in *NKX2.5* not only cause a developmental ASD, but also progressively disrupt electrical conduction through the cardiac chambers and can result in sudden death later in life (145,179). The AV node, which serves as the essential site of electrical communication between the atria and ventricles, is smaller than normal in adult *Nkx2.5* mouse mutants; over time, the specialized muscle-derived conduction cells are lost and replaced by fibrotic tissue, resulting in progressive defects in electrical conduction (147).

Another example of a congenital heart malformation causing disease later in life involves the aortic valve. Worldwide, 1% of the population is born with a BAV, typically silent in childhood (1). However, one-third of BAVs develop premature age-dependent calcific stenosis, resulting in poorly mobile, nonfunctioning valves, often in the fifth, sixth, or seventh decades of life (180). As a result, calcific aortic stenosis (AS) is the third leading cause of heart disease in adults and requires >30,000 surgical valve replacements per year in the United States. The recent discovery that *NOTCH1* mutations in humans cause BAVs and later calcification provides firm genetic evidence that the early developmental and later degenerative disease share a common genetic cause (134). Some family members with *NOTCH1* mutations had normal tricuspid aortic valves but still developed calcification, supporting the idea that the premature and severe calcification was primarily due to the genetic mutation itself rather than to hemodynamic effects on the valve leaflets.

Calcified human valves are characterized by ectopic osteoblast-specific gene expression suggesting a cell fate change of mesenchymal or inflammatory cells (180,181). Interestingly,

developing heart valves have a surprisingly similar gene expression profile to osteoblast progenitor cells (182). *Notch1* can repress a central transcriptional regulator of osteoblast cell fate, *Runx2/Cbfa1* (183), suggesting a potential mechanism through which *NOTCH1* normally suppresses calcification in the valve tissue (134). It will be interesting to determine if polymorphisms in *NOTCH1* are associated with altered risk of aortic valve or even vascular calcification, given the similar osteoblast gene expression in atherosclerotic vascular smooth muscle (184). If so, it is attractive to imagine effective preventive interventions over decades with pharmaceuticals, such as statins, to lower levels of cholesterol, a well-known risk factor for calcification (185).

CARDIAC STEM CELL AND REGENERATIVE APPROACHES

The notion that genes involved in the early formation of the heart may be redeployed to help protect, repair, or regenerate cardiac muscle has been a driving force in efforts to understand early developmental pathways (186). Reports describing niches of small, noncardiomyocyte populations in the postnatal heart that on isolation in culture could differentiate into cardiac muscle and endothelial cells initially generated considerable excitement that the heart, like other organs, may have a resident pool of progenitor cells (187–189). A subsequent population of progenitors expressing the developmental transcription factor *Isl1* further suggested an important connection between postnatal progenitor cells and an early developmental pathway regulating cardiomyocyte precursors. As described earlier, *Isl1* is expressed in SHF cells before they differentiate into myocytes and is down-regulated on expression of sarcomeric proteins. Cell fate studies suggest that cells derived from *Isl1*⁺ progenitors populate most of the RV and outflow tract and *Isl1* is required for the formation of these regions; some cells derived from these *Isl1*⁺ cells also contribute to the atria and left ventricle. In mice and humans, niches of *Isl1*⁺ cells are detectable in the early postnatal heart and may be remnants of developmental progenitor cells among terminally differentiated myocytes (27). However, isolation and characterization of these cells has proved elusive and the clinical utility has remained minimal. Interestingly, intrinsic cardiac progenitor cells appear to be much more abundant in neonatal human hearts raising the possibility that utilization of the cells may be particularly advantageous in treating congenital cardiac abnormalities in the early postnatal period (190).

Perhaps the most exciting observation in terms of developing cells that might serve as a source for myocardial regeneration and repair was made by Yamanaka (191), and colleagues, who demonstrated that skin fibroblasts from mice and humans (192) could be reprogrammed or “induced” to form pluripotent cells (iPS) via infection with viruses carrying four transcription factors (*Oct 4*, *Klf4*, *Myc*, *Sox2*) that were known to regulate pluripotency of ES cells. These cells could then be differentiated into various cell types representing derivatives from all three germ layers, including cardiomyocytes. The ability to derive iPS cells from patient that can then be differentiated to specific cell lineages has provided never before realized potential for disease-specific modeling, therapeutic pharmacologic screening, and myocardial-specific regeneration. Exploiting and maximizing the potential of iPS cells will require mining the extensive foundation of knowledge that has resulted from in-depth studies of embryonic cardiac development and ES cell differentiation (193) (Fig. 24.10). Interestingly, recent preliminary studies suggest that it may be possible to derive myocytes directly from fibroblasts (direct reprogramming) without having to first generate a pluripotent intermediate (194). This exciting observation raises the possibility of transforming

Figure 24.10. The developmental process serves as a guide for stage-specific cardiogenesis, which is characterized by changes in embryonic morphology. The gene-expression profiles that correlate with embryonic stages and differentiation of pluripotent stem cells provide a gauge for acquired cardiogenic potential from mesoderm to cardiac tissues. iPS cells from both humans and mice have the potential to mature through all of the early stages of cardiogenesis. Whether they can reach a mature, differentiated phenotype remains to be determined. iPS cells that can be programmed to distinct stages of cardiogenesis in order to secure reproducible therapeutic outcomes, validate diagnostic criteria, or provide reproducible discovery model systems are critical in order to realize the potential of these cells in discovery, diagnosis, and therapeutic intervention. dpc, days post coitum; iPS, induced pluripotent stem; MyHC, myosin heavy chain. cardiac fibroblast into myocytes in situ providing a more immediate therapy for injured myocardium.

SUMMARY

The field of cardiac developmental biology has progressed rapidly over the last decade, and the heart is now one of the best understood organs at the molecular, physiologic, and anatomic levels. Advances in human genetic tools have also led to a deeper understanding of the importance of developmental pathways in human disease. CHD can now be conceived as not only a defect of morphogenesis, but in some cases, a failure of differentiation among subsets of lineages that contribute to the heart. We are now embarking on a phase in which knowledge of developmental pathways and high-throughput methods of genotyping rare and common gene variants should allow rigorous investigation into the causes of human heart disease. With the increasing recognition that CHD has a significant genetic contribution, we can now imagine that genetic variation underlies both the morphogenetic defect and the predisposition to long-term consequences that will affect clinical outcomes for the millions of CHD survivors. Thus, vigorous efforts to identify genetic variation associated with CHD and outcome will be essential as therapeutic

or preventive measures to alter the course of disease may be possible throughout childhood and in the adult. It may even be conceivable to eventually predict genetic risk among parents and focus preventive strategies on those at greatest risk to transmit disease vertically. The efficacy of folic acid in prevention of neural tube defects provides hope for similar prevention of congenital heart disease (195,196).

As the next phase of disease-related biology evolves, parallel advances in stem cell biology should usher in an era of new approaches. It is exciting to realize that we are now able to generate disease-specific iPS cell lines for mechanistic studies of disease etiology and development of patient-specific progenitor cells for ultimate treatment modalities. Although it may become possible to guide progenitor cells into a cardiac lineage based on our knowledge of early developmental pathways, many hurdles must be overcome for therapeutic use. Issues such as cell expansion, delivery, incorporation, electrical coupling, and safety remain to be addressed. Despite these significant challenges, there is reason for optimism as we continue to unravel the mysteries surrounding the lineage determination, differentiation, and morphogenesis of cardiac cells. However realization of the potential of these studies will demand a closer collaboration between clinicians and basic scientists and will require the development of physician scientists with an intimate knowledge of developmental biology, genetics, and clinical congenital heart disease.

Epidemiology and Prevention of Congenital Heart Defects

Lorenzo D. Botto

FROM EPIDEMIOLOGY TO PREVENTION: INCENTIVE, EVIDENCE, STRATEGIES, TOOLS

Following the birth of a baby with a congenital heart defect, many anxious parents, some sooner and some later, will ask three crucial questions: “What will happen to my child?” (outcomes), “why did this happen?” (causation), and “will it happen again?” (risk).

These three questions—on outcomes, causes, risk—continue to challenge clinicians and public health professionals. While it may not be obvious, these questions are in fact linked, if viewed from the perspective of prevention. For primary prevention, this is clear: by eliminating established causes, primary prevention reduces the risk for affected pregnancies and prevents the associated adverse outcomes through the lifespan. Examples of effective primary prevention abound in pediatrics: immunizations are long-lasting interventions that prevent infectious diseases (including rubella-induced heart defects), whereas daily folic acid use is an ongoing intervention that prevents most cases of spina bifida and anencephaly, two serious birth defects. But prevention is also meaningful for people born with heart defects: by preventing complications and promoting optimal health, this form of prevention (sometimes called secondary prevention) also improves outcomes, though less completely than primary prevention. The main focus of this chapter is primary prevention. It is an overriding goal for pediatric cardiologists and the ideal and fundamental approach to decreasing the personal and societal burden of congenital heart defects. If *primary prevention is the goal, epidemiology is the indispensable tool*. Epidemiology evaluates risk factors, diseases, and outcomes in human populations: it takes the findings from basic research and clinical studies and translates them into meaningful information for populations. Using D-transposition of the great arteries as an example, epidemiologic studies can assess its impact in terms of deaths, hospitalizations, or cost; disparities in outcomes by race-ethnicity or socioeconomic status; and the fraction of cases due to maternal diabetes and preventable by careful metabolic control in the preconceptional period. Epidemiologic studies can also take the causal discoveries in experimental animals, cell cultures, or biochemical pathways and see how they translate into health effects in humans—for example, using population-based case control studies to measure the etiologic impact of specific genetic and environmental factors in human populations.

In this sense, epidemiology, although it has strong theoretical underpinnings, is fundamentally a practical tool. Epidemiology provides data for action and in particular for prevention. Figure 25.1 illustrates this point and provides a roadmap of how the epidemiology of congenital heart defects is discussed in this review. Specifically (Fig. 25.1), epidemiology supports and promotes four interrelated elements of the prevention process: *incentive, evidence, strategies, and tools*.

Incentive refers to the overall impact of heart defects on people and society: persons affected, lives lost, chronic illness, disability, health disparities, decreased quality of life, loss of productivity, and costs. Epidemiologic studies generate many of these metrics, which in turn provide the *policy and moral basis* for prevention. In fact, the current impact of congenital heart defects illustrates the very real cost of doing nothing, or not doing more, to prevent these heart defects. When interventions are implemented, these same metrics provide baselines against which to assess the effectiveness of actions and policies. As will become clear, the current overall impact of congenital heart defects through the lifespan is probably underestimated, mainly because of significant data gaps. Developing more realistic, timely, and population-based estimates of the overall impact of congenital heart defects can help make the case for greater investment into research and prevention.

Once the incentive is documented and understood, the *evidence* for prevention must be robust and convincing (Fig. 25.1). Such evidence provides the *science for action*. Particularly important is the evidence relating to modifiable risk factors, including maternal conditions and environmental exposures. Epidemiologic studies can help build the evidence for prevention: well-designed studies can help identify and characterize risk factors in human populations and generate useful metrics such as relative risks, absolute risks, and attributable fraction (the fraction of cases preventable by reducing the exposure). To be actionable, these data must be authoritatively reviewed and timely, so that interventions can be implemented promptly and improved quickly. Of course, susceptibility genotypes are likely important modifiers of environmental and maternal risk factors; however, the science is still incomplete and its use, particularly in resource-poor countries, will likely continue to be challenging and expensive. Once incentives and evidence are established, prevention needs effective *strategies* and useful *tools* for implementation and evaluation (Fig. 25.1). Effective, high-impact strategies are typically multitiered, from interventions that tackle the global socioeconomic determinants of health to individual health care delivery such as education and counseling. They are typically also person centered, rather than organ specific. One example is preconception care that focuses not only on cardiac risk factors but promotes women's health overall. Strategically, prevention should have maximum population impact for a given amount of resources. For this reason, it also is helpful to assess risk factors by their attributable fraction, as a measure of their contribution to congenital heart defects in the population. This epidemiologic metric is a nonlinear function of the relative risk for congenital heart defects combined with the prevalence of the risk factor in the population. Well-designed epidemiologic studies can provide these estimates and thus help the development of effective and efficient policies.

Finally, effective strategies need to be implemented in ways that are sustainable and pervasive. This requires tools and technologies that are practical and easy to use. A simple example

Figure 25.1. From epidemiology to prevention: incentives, evidence, strategies, and tools.

could be a screening questionnaire for use in a busy clinic, to be filled out in the waiting room at every visit, aimed at identifying major risk factors for congenital heart defects in a family. Items flagged in the screening can then prompt further evaluation, education, or referrals. A more complex tool for prevention could be a population-based, country-wide surveillance system, which can be used to assess changes in prevalence, adverse outcomes, or risk factors for congenital heart defects. Such a system would generate timely, ongoing epidemiologic information that will help monitor the effectiveness of prevention. This last example also underscores the circular nature of the four elements of prevention (Fig. 25.1): occurrence and outcomes start out as incentives for prevention, the evidence of causal determinant is generated, effective prevention strategies are developed, tools are designed and used in implementation, and finally occurrence and outcomes are again evaluated to continuously improve prevention, bringing the process to full circle.

In summary, this review focuses on selected epidemiologic aspects of congenital heart defects and discusses their relevance in the broader context of primary prevention (Fig. 25.1). The discussion makes use of material from several reviews, where additional information on epidemiology and risk factors can be found (1–5).

OVERARCHING ISSUES: LIFESPAN PERSPECTIVE AND CODING/CLASSIFICATION

Before examining incentive, evidence, strategies, and tools, it is helpful to address two overarching issues—lifespan perspective and classification/coding—that have important implications for any approach to the epidemiology and prevention of congenital heart defects.

Lifespan, Person-Centered Perspective

A lifespan perspective views a person's life as a continuum, from preconception to adult life and beyond (Fig. 25.2). This perspective provides a helpful framework to assess needs and data gaps for the many issues that arise during the lifespan (1).

Three concepts are particularly important. First, the true impact and relevance of congenital heart defects become clear only when viewed and measured throughout the lifespan. For example, issues such as diagnosis and early treatment are more relevant earlier than later in life, but prevalence remains an important issue for clinical care throughout life. Schooling, employment, and social integration become increasingly important as children grow into adults. At the opposite end of the lifespan, risk assessment and prevention are best assessed in the preconception period. Finally, some issues such as the personal and societal costs, while perhaps high in children, are best evaluated over an entire lifespan, particularly in the current era of improved survival and longer life expectancy. Taking a person-centered, lifespan perspective helps appreciate the many connections among apparently dissimilar issues; for example, quality of life is connected to the quality and timeliness of diagnosis, treatment, and management, and also to the associated complications, disabilities, caregiver stress, cost, and social integration.

Historically the epidemiologic assessment of occurrence and outcomes has focused on newborns and young children, typically looking at one element at the time (e.g., prevalence and mortality). Thus, a second important concept (Fig. 25.2) is that our current view and knowledge are in many ways partial and skewed, with emphasis on the time of birth and early childhood but progressively incomplete and uncertain as the focus shifts backward into pregnancy and preconception (e.g., risk factors) or forward into adult life. In part, this situation is understandable. Birth and infancy are critical periods in life when many diagnoses are made and crucial medical and surgical management is initiated. Also, information on this period is more readily available, because most of these activities take place in hospitals where data on diagnosis, morbidity, and mortality are more easily collected and shared. But—and this is the third important concept—as one moves away from birth and infancy, the issues not only become more complex, but also the data and data systems needed to capture them become more difficult and complicated to acquire. Thus, a major challenge for epidemiology and prevention is that significant data gaps are found precisely for those issues that are more numerous and more complex (Fig. 25.2). Meeting this challenge will require a major, long-term, and coordinated

Figure 25.2. Lifespan, person-centered perspective: issues, knowledge, complexity.

effort of epidemiologist, clinicians, and health administrators; the benefits would be considerable, including having global and accurate basis to plan, implement, and evaluate clinical services and prevention.

Coding and Classification

Coding and classification are related but different processes. Typically, coding translates words from a clinical description into well-defined descriptive codes, which then can be used for data sharing and epidemiologic analysis. By moving from description to a limited set of codes, coding usually entails a loss of information. One challenge for a coding system is to retain the essential information while discarding the inessential. However, what is essential in one application may not be essential in others. For example, information on surgical procedures or severity of a valvar stenosis is essential in an outcome study but not as much in an etiologic study.

Classification is typically a higher order process. It can start from descriptions or even codes, and then uses a set of explicit criteria to group cases or phenotypes into meaningful analytic groups. Thus, the same (coded) cases can be classified differently depending on whether the classification emphasizes pathogenetic principles (e.g., neural crest origin), similarities in outcomes (e.g., mortality), or anatomy (e.g., cardiac segment involved). Also, whereas a given person may be assigned multiple descriptive codes, many classification systems try to map each person to one primary group. In practice, many coding systems are designed also with a default classification structure, which is typically hierarchical and based on the code's digits.

Coding and classification are crucial because they are the basis for all epidemiologic analyses: decisions, inconsistencies, or errors in coding and classification can affect findings significantly. In fact, part of the challenge of comparing and aggregating data is the variation or uncertainty in coding and classification among different studies.

To illustrate some of these issues, it is helpful to briefly review two commonly used coding system used for many applications—the World Health Organization (WHO)'s International Classification of Diseases (ICD) system, and the Society of International Surgeons (STS) system—and a classification system based on principles of pathogenesis and implemented in several etiologic studies (Table 25.1).

The WHO's ICD system is used by health care systems worldwide to generate epidemiologic data, including prevalence and mortality, for many diseases. The ICD is now in its 10th edition with the 11th in preparation, though the 9th edition is still widely used in several countries with some clinical modifications. The ICD system for congenital heart defects is mainly based on anatomy. The hierarchy of codes tends to group by regional anatomy. For example, left obstructive heart defects are dispersed across different high-level groups, depending on whether the structure affected is the mitral valve, the aortic valve, or the aorta. As an all-purpose system, the ICD system has known limitations in its ability to code the more complex cardiac defects or to distinguish degrees of severity of a given lesion, and these limitations are particularly felt in studies of etiology and outcomes. Nevertheless, many birth defect registries and epidemiologic studies still use this system, often incorporating the clinical modifications developed for ICD-9 and ICD-10 by the British Paediatric Association (BPA), now the Royal College of Paediatrics and Child Health.

Understanding the limitations of the available systems of coding and nomenclature for congenital heart defects, several leading cardiology organizations have worked to develop new systems that could be used internationally and typically with a focus on supporting large-scale outcome studies with systematic risk stratification. An important step has been the establishment of the International Society for Nomenclature of Paediatric and Congenital Heart Disease (6). One product has been the International Paediatric and Congenital Cardiac Code (7). This coding system is available for free (8) and captures not only the anatomy but also the clinical correlates and procedures.

TABLE 25.1

Coding and Classification Systems for Congenital Heart Defects: Approaches and Examples

	Epidemiologic	Clinical	Etiologic/Pathogenetic
Focus	Coding	Coding	Classification
Example	ICD-International Classification of Diseases and variants (BPA)	International Paediatric and Congenital Cardiac Code	Clark-Pathogenetic Classification and variants
Used by (examples)	Many health systems worldwide, including birth defect registries	STS; EACTS-European Association for Cardiothoracic Surgery; others	NBDPS; BWIS; others
Basis	Anatomy (regional)	Anatomy, severity, procedures	Embryology, developmental mechanisms
Main uses	Assess frequency, patterns, basic outcomes (cause of death)	Evaluate outcomes, treatment, incorporate risk stratification	Find causes, risk factors
Approach	Code each finding, without prioritization	Codes clinically relevant lesions and procedures	Select one main diagnosis per baby; selection is hierarchical, based on earliest developmental event
Strengths	1. International standard, widely used, provides basic metrics for many countries;	1. Incorporates clinically relevant details (e.g., severity, surgery), to improve clinical homogeneity in outcome studies;	1. Incorporates developmental mechanisms and timing, likely relevant in pathogenesis;
	2. Can include clinical modifications;	2. Ongoing efforts for international diffusion and collaborative development	2. Provides a main “pathogenetic” phenotype for each person (one person = one diagnosis);
	3. Updated, maintained by major international body (WHO)	3. Can be mapped to other systems	3. Provides rationale for aggregating (lumping) anatomic phenotypes to increase ability power to detect associations with risk factors (e.g., LVOTO)
Challenges	1. Limited specificity for rare, complex conditions;	1. Required clinical details typically available in medical records but not (yet) in administrative records;	1. Developmental mechanisms still incompletely understood;
	2. Inability to specify degree of severity by lesion	2. Requires careful standardization of description, coding, and reporting across clinical centers	2. Will require revisions as understanding of pathogenesis evolve

LVOTO, left ventricular outflow tract obstruction.

As a dedicated system developed by a team of topic experts, this system has many strengths (Table 25.1) and is used in surgical centers internationally. One caveat is that it could be complex to implement in birth defect registries or administrative settings with limited case information and cardiologic expertise. However, with cardiology expertise, this system could be used in birth defect surveillance, as shown by recent pilot implementation studies (9,10). Finally, interactions between those responsible for the ICD and for the International Nomenclature codes may lead to improvements in the cardiac codes of the next editions of the ICD. Because of the widespread use of the ICD, such changes have the potential to improve the basic epidemiologic information from administrative data bases worldwide (6,7).

By contrast, some systems focus explicitly on classification, rather than coding, and on specific grouping principles. One of these systems (Table 25.1) was developed and updated by Dr. EB Clark (11,12) and is based on pathogenetic and mechanistic considerations, rather than anatomy or clinical

outcomes. Its main use is in etiologic studies. An explicit goal is to improve a study's ability to identify associations between risk factors and congenital heart defects. In such studies, a specific challenge is balancing phenotypic detail with sample size: one must avoid defining groups so narrowly that each group has too few cases (thus losing statistical power and missing associations), while not incurring in the opposite error, making groups so broad that heterogeneous conditions are lumped (thus also underestimating or missing associations). By grouping pathogenetically similar heart defects (e.g., left side obstructive defects), sample size is increased while preserving pathogenetic homogeneity. One important aspect of this system (and of many classification system) is that, to the extent possible, one principal pathogenetic group, the one thought to be more basic or occur earlier in development, is assigned to each affected person, regardless of the number of cardiac malformations (or ICD/STS codes). The groups, mechanism, and hierarchy are summarized in Table 25.2.

Aortic valve stenosis

Coarctation of the aorta

Interrupted aortic arch type A

Hypoplastic left heart, aortic atresia/mitral atresia

Right heart defects

Bicuspid pulmonary valve

Secundum atrial septal defect

Pulmonary valve stenosis

Pulmonary valve atresia with intact ventricular septum

Perimembranous ventricular septal defect

Cell Death Abnormalities

Muscular ventricular septal defect

Ebstein malformation (hierarchically placed before intracardiac blood flow defects)

Assigning a principal diagnosis is not always straightforward. One solution in the National Birth Defects Prevention Study (NBDPS) was to create specific groups for common associations, such as atrial septal defects and pulmonic stenosis (13). Other systems assign multiple defect categories to the same baby (14) or add dimensions to the classification scheme (15). Typically, the need to consider multiple diagnoses is more of an issue in outcome studies, where they can be important for risk stratification, than in etiologic research, where in fact having a meaningful principal diagnosis is a methodologic strength.

In its original form or with modifications, the pathogenetic classification has been used in several large epidemiologic studies, including the Baltimore-Washington Infant Study (BWIS) (16,17) and in some analysis of the Atlanta Birth Defects Case Control Study (18,19). Currently it has been incorporated into the cardiac classification of the NBDPS, one of the largest ongoing case control studies on the etiology of birth defects (13). In an extension of the original system, the NBDPS classification system also stratifies phenotypes based on whether the heart defect is simple, an association, or complex (13). The purpose is to identify a subset of “pure” groups of heart defects, defined as simple phenotypes in individuals without extracardiac anomalies. By minimizing anatomic and pathogenetic heterogeneity, this approach aims at improving the ability to find meaningful associations with risk factors. The other cases are still used, but are incorporated later or analyzed separately. This approach is most practical in large studies of cases with accurate clinical description of both the baby and the heart.

Finally, these pathogenetic classifications are best implemented starting from verbatim diagnoses, but, within limits, could be used starting from codes. For example, the International Paediatric and Congenital Cardiac Code/STS codes can be mapped to the NBDPS and Clark Classifications, and such hybrid systems can in principle retain the clinical precision of the former and the pathogenetic perspective of the latter (9).

In summary, this section briefly described two overarching issues—lifespan perspective and classification/coding—that have substantial implications for epidemiology and prevention of congenital heart defects. Embracing a lifespan perspective leads to realizing that our current view of congenital heart defects still misses important aspects in the lives of affected people and their families, and in doing so, underestimates the true impact of such heart defects in people, families, and society. Filling these data gaps is a major undertaking. Classification and coding are foundational elements of epidemiologic studies: they are the basis of any operational definition of what congenital heart defects are and how to group them in studies of occurrence, outcomes, and etiology. Clearly, substantial thought needs to go into their development and use. Also, using well-established coding and classification systems, or systems that can be explicitly mapped to them, will be very helpful when comparing and aggregating data across studies, thus promoting the progress of clinical care, service planning, and prevention. With these considerations in mind, the specific issues of heart defect epidemiology and prevention (Fig. 25.1) can be fruitfully discussed, beginning with “incentive.”

INCENTIVE FOR ACTION: EPIDEMIOLOGY OF OCCURRENCE AND OUTCOMES

The epidemiology of occurrence and outcomes generates key data to assess the true impact of congenital heart defects on individuals and society. Knowing the true impact provides the incentive for action, whether it is in the form of research, primary prevention, or prevention of complications in people

with congenital heart defects. Evaluating occurrence and outcomes, however, can be challenging. Selected issues and key findings are briefly reviewed.

Occurrence

The occurrence of congenital heart defects can be evaluated using incidence and prevalence. Technically, incidence measures the number of new cases among an initially disease-free cohort of at-risk individuals within a specific time frame. Although a good measure of the “force” of disease, incidence is difficult to measure for congenital heart defects. One difficulty is that the disease-free at-risk cohort is formed, strictly, by conceptuses, whose number cannot be estimated with any accuracy (20). Prevalence, on the other hand, reflects the occurrence of disease at a point in time in a defined population. Prevalence therefore can be estimated for fetuses at a certain gestational age, stillbirths, newborns, children, adults, or a combination of these.

Because it can be computed with easily available data, prevalence at birth—the number of babies born with a heart defect divided by the total number of babies (usually live births) in that period—is frequently used as a basic epidemiologic measure of occurrence (20). However, by not including early pregnancy losses, birth prevalence will underestimate the global impact of congenital heart defects.

Published estimates of birth prevalence vary considerably (4,21,22), even in fairly recent studies (14,23–37). A crucial question is to what extent such variation is real or due to methodology. Real variations can provide valuable clues to causation. Variations due to methodology, however, are usually a hindrance: they can complicate many activities, from surveillance to outcome assessment to evaluation of the prevention activities. In practice, methodologic factors certainly play a role in reported rates. To understand the role of these factors, one needs to review carefully aspects such as diagnostic practices, case definitions, case classification, inclusion of pregnancy terminations, timing of diagnosis (fetal, birth, or childhood), length of follow up, and reporting procedures (4,21,22,38). For example, in a recent study from a European network of birth defect registries, birth prevalence varied considerably by country, even with systems using the same central database and procedure protocols (36). These variations are likely systematic rather than due to chance, so that taking the average across programs has limited value (an average is a good approximation when the cause of the variation is random error, not systematic bias).

Several studies published since the 1980s (14,23–36,39) on the prevalence of fetal deaths (stillbirths), newborns/infants, and children with heart defects are illustrated in Figure 25.3.

This figure helps to highlight several points. First, most studies focus on newborns and infants. Limited data are available on fetuses, older children, and adults. While understandable, because of the greater difficulties of population studies outside of the newborn period, this scarcity of data signals an important gap to fill. Second, heart defects appear to be more common among fetal deaths than in other groups. In the three studies, from the United States and France (23–25), the reported prevalence of heart defects among fetal deaths ranged from 13 to 35 per 1,000. The higher figure, from the larger and more recent study (25), is probably closer to reality. Of note, fetal deaths are as common as infant deaths in many developed countries, yet their environmental and genetic determinants are not well characterized. Third, the estimated prevalence in newborns and infants, based on many studies, varies widely by area and reporting program, from approximately 3 to 14 per 1,000. A more detailed analysis of three of these studies (Table 25.3) can help clarify what drives the

prevalence of congenital heart defects and the variations that are commonly observed.

In the BWIS, investigators in the North-Eastern United States implemented in the 1980s a population-based study of live births with heart defects, with follow-up through 1 year of age. The BWIS was primarily designed as an etiologic case-control study, but because of the high quality of ascertainment, investigators generated a set of birth prevalence estimates that have been often cited since (of note, ventricular septal defects may have been sampled rather than exhaustively included) (16,17). The second study, from the Centers for Disease Control and Prevention (CDC)'s Metropolitan Atlanta Congenital Defects Program (MACDP), reported rates of heart defects from 1998 through 2005 from four counties in a large metropolitan area in the South-Eastern United States (14). BWIS and the MACDP, though not identical, have some broad operational similarities, including active ascertainment from multiple sources, follow-up period through early infancy, and a similar though not identical case classification. MACDP also includes stillbirths and pregnancy terminations. The third study, from Trondheim in northern Norway, combined systematic assessment with prenatal diagnosis to identify heart defects starting from before birth (35). Specifically, these researchers systematically evaluated by prenatal echocardiography a large, unselected cohort of pregnancies from a well-defined geographic area, first at midgestation, then postnatally, with follow-up through 2 years of life.

Side-by-side comparisons are not completely accurate because the defect groups in the MACDP report were not mutually exclusive: approximately 10% of babies were assigned more than one main defect group and are therefore counted multiple times in the categories of Table 25.3 (14). Nevertheless, some broad considerations can be made. First, these three studies report different overall rates of heart defects, with a nearly threefold difference between the lowest (48 per 10,000 in BWIS) and the highest (146 per 10,000 in Trondheim) estimate. Second, these overall differences are largely due to a few common defects, mainly ventricular septal defects and to a lesser degree atrial septal defects and pulmonic or aortic valve stenosis. The potential for variable ascertainment and reporting of these defects, particularly their mild forms, is significant. In fact, in the Norwegian study nearly all (96%) of the ventricular septal defects were considered minor. Other studies support the notion that diagnostic intensity can significantly influence the reported rate of these defects. In one study from Japan (40), for example, 2% of an unselected cohort of newborns had a ventricular septal defect when evaluated sys-

tematically at birth by Doppler ultrasonography. Most of these were small muscular defects, only about half had an associated murmur at hospital discharge, and three-quarters closed spontaneously by 1 year of age (40). A second study also from Japan (41), using similar methods in a cohort of 2,067 newborns in the first 4 days of life, reported a 5% overall birth prevalence of heart defects (503 per 10,000); however, most cases were small ventricular septal defects and patent ductus arteriosus (41), and over half were said to be asymptomatic and did not require intervention. In addition to septal defects, some valvar abnormalities are also variably ascertained and reported. For example, extrapolating from limited data, investigators have estimated that bicuspid aortic valve has a prevalence of about 0.5% in babies (500 per 10,000) (42) and perhaps of 1% to 2% in adults (43). Other defects that can contribute significantly to rate variations include small atrial septal defects (sometimes difficult to differentiate from patent foramen ovale) and patent ductus arteriosus, particularly in preterm infants or in the early newborn period. Although some studies report how these minor defects have been dealt with, this is not always the case, adding to the challenge of interpreting and comparing findings.

In addition to variations by study and program, some temporal trends have been noted in several studies. Many studies (Fig. 25.3) published in the earlier part of the 1980s tended to report a birth prevalence of heart defects between 4 to 6 per 1,000, whereas studies published in more recent years reported rates closer to 8 to 9 per 1,000, sometimes higher (14,28,35,39,44). Direct evidence for time trends within the same reporting program has also been reported in several countries (15,39,45). These studies show two main findings. First, reported rates increased the most for the clinically milder defects, compared to the more severe defects. Second, the time frame of these trends roughly coincides with the increasing use of echocardiography: rates rise quickly in the 1980s and slow considerably, sometimes to a plateau, in the 1990s (15,39,45). An example of such pattern is illustrated in Figure 25.4, focusing on right-sided obstructive defects in Metropolitan Atlanta (39).

In that study, reported rates increased roughly in proportion to the severity of these defects. The rise was sharpest and highest for peripheral pulmonic stenosis, less for valvar stenosis, and minimal for pulmonary atresia with intact septum (39).

These data in the aggregate indicate that most of variations observed between programs is driven by ascertainment and reporting, mainly (but not only) of less severe heart defects. A related factor, now of greater importance than in the past, is prenatal screening and diagnosis. In many developed

Figure 25.4. Trends in birth prevalence of selected right-sided obstructive heart defects, Metropolitan Atlanta. (Data from Botto LD, Correa A, Erickson JD. Racial and temporal variations in the prevalence of heart defects. *Pediatrics* 2001;107:E32.)

countries, most pregnant women undergo a prenatal ultrasound examination, sometimes several times during the pregnancy. Depending on the type and intensity of prenatal examinations, the fraction of congenital heart defects that are diagnosed before birth can be substantial, particularly those that can be detected with simpler screening views (e.g., four-chamber) by practicing obstetricians. In the Norwegian study, for example, the high prevalence of heart defects (Table 25.3) is likely also due to the study's systematic prenatal assessment, possibly augmented by the identification of cases of chromosomal anomalies such as Down and Turner syndromes that have a high fetal mortality and may be overrepresented in fetuses compared to live born infants.

In summary, available data strongly supports that the observed variations in the birth prevalence of heart defects are mainly due to methodology rather than biology. Biology may play a role, but probably a minor one. For example, rates of selected heart defects vary to some degree by race and ethnicity as well as sex: studies from different countries quite consistently document higher rates of D-transposition of the great arteries and aortic stenosis in boys than in girls, and in non-Hispanic whites than in non-Hispanic blacks (14,30,39,46,47). However, these variations, while helpful as clues to etiology, would explain at most a very small fraction of the rate differences among studies.

Prevalence Beyond Infancy and Early Childhood

Compared to birth prevalence, the prevalence of congenital heart defects in older age groups is much less known (Fig. 25.3). For example, an early estimate from the American Heart Association put the number of adults with congenital heart defects at one million adults (or ~1 in 300 people), but was based on very little data. A more formal estimate, published in 2001 by a task force convened by the United States National Institutes of Health (NIH) (48), estimated that in 2000, 1 in 350 people in the United States was an adult with a congenital heart defect (or ~800,000 in total), with about half of these having a moderate or severe heart defect (Fig. 25.5).

These numbers were generated not from direct population surveys of adult patients but from mathematical models that combined birth prevalence data with estimated survival rates to estimate a cross-sectional snapshot of people of different ages living to the year 2000. Of note, these estimates indicated that the number of adults with congenital heart defects surpassed that of children. In fact, using the total United States population as the denominator (275 million people), the data from NIH-convened panel suggested that 1 in 195 people

(children and adult combined) living in the United States in the year 2000 had a congenital heart defect.

These estimates are important for several reasons. Although not based on actual surveys done in the different age groups, the figures generated by mathematical modeling used reasonable assumptions on birth prevalence and survival by broad groups of heart defects. These estimates also tried to incorporate the typical life course of common congenital heart defects; they assumed, for example, that most instances of ventricular septal defect and patent ductus would have resolved by adulthood, thus decreasing their prevalence in adults compared to children. The grouping of heart defects (simple, moderate, and severe) was also meaningful: these categories, based not only on anatomy but also associated procedures and likely outcomes, tried to reflect overall clinical needs, thus providing some basis for planning services for adults with congenital heart defects. Also, as noted, the higher number of adults than children with congenital heart defects emphasizes the need for specialized adult services in the community. Finally, the very fact that modeling was required to generate these estimates highlights the current, significant data gaps and the crucial need to have systems in place to gather valid primary data.

More recently, studies have begun to directly assess the prevalence in older children and adults. Typically, this has been possible in countries other than the United States, with population-based integrated health care systems and databases. For example, researchers in Quebec linked two large provincial healthcare databases (49) to identify people of all ages who had encounters with the health care system for congenital heart defect diagnoses or procedures. The resulting estimates of prevalence in adults and children were in the range of those modeled in the earlier United States study. As a fraction of the overall Quebec population in 2000, 1 in 165 people had a congenital heart defect: 1 in 288 was an adult with a congenital heart defect and 1 in 388 was a child (<18 years) with a congenital heart defect (49). This study also noted an increasing prevalence over time of the prevalence of congenital heart defects in both adults and children. Even taking into account the limitations of administrative databases, this is an important study because it directly evaluated the number of people with congenital heart defects in a population-based setting.

Whereas it is tempting to extrapolate these findings to the United States and other developed countries, it is important that each country develops the resources to perform these studies on an ongoing basis. Also, these estimates, while very important, are only the beginning, as they reflect the past rather than the present. For example, according to both the United States and Quebec studies (48,49), the number of adults with congenital heart defects is projected to increase with time, perhaps by 5% per year (50). Including conditions such as bicuspid aortic valve, the rate of significant disease in adults could be even higher (43,51–53).

In summary, for the first time the high and increasing numbers of adults with congenital heart defects is being actually documented. Significant gaps still remain. Crucial needs include ongoing monitoring of these trends, improving data quality (including validation), and expanding data coverage to the entire population. This information will be extremely helpful in evaluating and meeting clinical needs, particularly in adults, and evaluating prevention—in short, in moving “from numbers to guidelines” (48,49,54,55).

Improving Occurrence Data

This brief review of the occurrence of congenital heart defects, including prevalence at various ages, highlighted several methodologic challenges that can limit the usefulness of the data for planning and prevention. Many of these challenges are solvable in principle (Table 25.4).

Figure 25.5. Number of adults and children (and rate per total population) estimated to live with a heart defect in the year 2000, by severity of congenital heart defect. (Data from Warnes CA, Liberthson R, Danielson GK, et al. Task force 1: the changing profile of congenital heart disease in adult life. *J Am Coll Cardiol* 2001;37:1170–1175.)

TABLE 25.4

Prevalence of Congenital Heart Defects: Importance of Person, Place, Time, and Implications for Prevention

Issue	Comment and Implications
Defining heart defects	<p>Evaluating heart defects in the aggregate has limited value: rates of clinically minor defects drive overall rates and depend critically on diagnostic and reporting intensity, etiology and prevention are unlikely the same across all types of heart defects, and the benefits of prevention are also a function of clinical severity.</p> <p>More informative to study, report, and monitor specific types of heart defects or, at a minimum, well defined classes of heart defects, defined by severity or pathogenesis, depending on the goal of the study.</p> <p>Exclusions, coding and classification affect findings, sometimes substantially: important to describe completely in report and use consistently.</p> <p>Separate isolated cases from multiple congenital anomalies and genetic syndromes.</p>
Geographic variations	Also driven mostly by clinical practice and reporting methodology. When evaluating trends after interventions, best to use the same area or program as baseline, to minimize the influence of methodologic issues.
Time trends	<p>Baselines and analytic techniques must be chosen carefully when evaluating prevention interventions (e.g., diabetes, flour fortification): preceding time trends need to be identified and adequately incorporated (typically requires statistical modeling).</p> <p>Trends can be valid, even in the presence of incomplete ascertainment, so long as the ascertainment fraction remains constant: methodologic consistency is key in longitudinal assessment.</p>

Briefly, in evaluating prevalence it is very helpful to think in terms of person, place, and time. In practice, this means clearly defining first the “person,” namely, the study population and the heart defects (including method of coding and classification, inclusion, and exclusions) in addition to data sources and reporting procedures. Defining “place” is also important, because of well-known geographic variations in prevalence. One implication of these geographic variations is that when evaluating interventions, it is crucial to have preintervention baselines that are local (this obvious step can be forgotten in the haste of implementing prevention strategies). Finally, the element of “time” is important not only as a reminder to assess temporal trends, but also to highlight the need to expand studies to adolescents, adults, and the elderly, so that their needs are better assessed and met.

WORLD PERSPECTIVE

With the caveats just described, some minimal generalizations can probably be made about the international occurrence of congenital heart defects. The aggregate data described so far (including those in Table 25.3) suggest a birth prevalence of approximately 2 to 3 per 1,000 for the clinically more severe conditions, increasing to 6 per 1,000 when including also moderately serious conditions (21), and summing to 9 per 1,000 to perhaps 15 to 20 per 1,000 when further including smaller septal defects and milder valvar stenoses (35,40). Adding bicuspid aortic valve might add another 5 to 10 per 1,000 cases to these estimates. In numbers, among the estimated 140 million births occurring yearly worldwide, the overall number of babies born with heart defects could be in the order of 1.2 million per year (9 per 1,000), of which approximately 300,000 to 400,000 will have what may be considered severe heart defects (2 to 3 per 1,000).

However, generalizing findings from relatively small study areas in a few developed countries to the rest of the world, while useful as a broad indicator of global impact, requires considerable caution. The best estimates from good studies in developed countries are probably a reasonable starting point (21,56–58), and have been used in the latest March of Dimes

global report on birth defects (59). In fact, because of the challenges of obtaining accurate data on congenital heart defects in resource-poor areas, such extrapolations are probably a better approach than relying on local data of lesser quality. Nevertheless, these extrapolations may underestimate the true numbers. The occurrence of congenital heart defects in developing countries may be higher than in developed countries for several reasons, including higher rates of consanguinity and greater exposure to nutritional, maternal, or environmental risk factors. From a prevention perspective, the large fraction of affected births from developing countries underscores the urgency for effective primary prevention, and in particular prevention that is comprehensive, inexpensive, and focused on modifiable risk factors associated with the largest fraction of disease in the population.

OCCURRENCE: THE FUTURE

As discussed, the prevalence in older children and adults is likely to increase for several years as survival rates improve worldwide. Prevalence at birth may also change over time. Some factors have already been examined, such as the more complete and earlier ascertainment of milder or minor heart defects. Additional factors that could have a significant impact on current rates and trends include pregnancy termination, universal neonatal screening, and changing prevalence of risk factors. A few examples are discussed by way of illustration.

IMPACT OF PRENATAL TERMINATIONS

A major challenge will continue to be the assessment of fetal deaths and pregnancy terminations with congenital heart defects. In some areas, pregnancy terminations account for a substantial fraction of cases of selected congenital heart defects. In a study of a selected group of European birth defect registries, with data through 2005, 6% of all cases of heart defects not associated with chromosomal anomalies were terminations of pregnancy, with variations across registries and type of congenital heart defect (36). In that study, the reported rate of prenatal diagnosis was fairly low (13%), suggesting that terminations of pregnancy could account for a higher fraction

Figure 25.6. Pregnancy terminations as proportion of all cases of hypoplastic left heart syndrome: selected birth defect programs of the International Clearinghouse for Birth Defects Surveillance and Research, 2007. (Data from International Clearinghouse for Birth Defects Surveillance and Research. Annual Report 2009, with data for 2007. In: Mastroiacovo P, ed. Rome, Italy, 2009.)

of cases in the future, as the prenatal diagnosis of severe cases increases. In a related study from the same database, selected heart defects, including hypoplastic left heart syndrome and single ventricle, contributed to late terminations of pregnancy, after 23 weeks of gestation (60).

The impact of pregnancy termination can be considerable in particular for certain heart defects. As an example, Figure 25.6 summarizes the data on hypoplastic left heart syndrome reported to the International Clearinghouse for Birth Defects Surveillance and Research for the 2007 birth cohort, including only programs that ascertain pregnancy terminations, had realistic overall birth prevalence rates (2 per 10,000 or more, see Table 25.3), and at least 10 or more cases of the condition (61).

In some areas, particularly in Europe, pregnancy terminations account for half or more of all cases of hypoplastic left heart syndrome. In North America, this fraction seems to be consistently lower, under 10%. Ascertainment of pregnancy terminations can be difficult and reported rates may vary for methodologic reasons as well. Nevertheless, these findings underscore how studies that fail to incorporate pregnancy terminations will underestimate the overall occurrence and impact of congenital heart defects. In etiologic studies, failure to include pregnancy terminations could introduce potentially significant biases; for example, if an exposure (e.g., smoking or medical use) is associated with the likelihood of a pregnancy termination. Finally, increasing pregnancy termination rates, if unaccounted for, can lead to an apparent drop in birth prevalence, and conversely, with fewer pregnancy terminations, birth prevalence may appear to increase and cause unnecessary community concerns. Systematically including pregnancy terminations in epidemiologic monitoring can help clarify these issues.

NEONATAL SCREENING

Universal neonatal screening by pulse oximetry has been proposed for the early detection of certain critical cyanotic conditions, and is already being implemented either clinically or in pilot studies, mainly in parts of North America and Europe (62–73). Leaving aside the advantages and challenges of this approach, which are still a matter of discussion, universal screening could speed the identification and reporting of selected severe heart defects. High-quality registries with

multiple sources of ascertainment through infancy would be unlikely to miss many such cases; in these areas, the birth prevalence of these heart defects would probably change little if at all, though some cases would be identified and reported earlier than before screening. Advantages for epidemiologic monitoring would be seen mainly in areas with only basic registries or none at all. In fact, universal screening, if properly organized, would create a valuable repository of information on selected major congenital heart defects for the entire screened population. Such population-based data would support some of the key clinical and public health activities on a much larger scale than has been possible so far, including monitoring trends, assessing outcomes, conducting etiologic studies, and evaluating prevention interventions.

CHANGES IN RISK FACTORS

Current population trends suggest that the prevalence of some known risk factors for congenital heart defects is changing. One example is the increasing maternal age in many developed countries. This could lead to an increase in pregnancies with heart defects associated with maternal-age dependent chromosomal syndromes. The increase would likely be small on a yearly basis, and probably undetectable unless the data are examined carefully. The prevalence at birth of these heart defects would also depend on the concurrent use of fetal diagnosis and pregnancy termination. As a risk factor, the population distribution of maternal age is difficult to modify, though education and preconceptional counseling could have an impact in individual situations. A more pervasive concern is the rise of some risk factors such as maternal pregestational diabetes, especially if untreated or unrecognized. As discussed in the section on risk factors, diabetes is already increasing in several countries: the combination of high frequency, increasing trends, and high teratogenic risk makes diabetes a clinical and public health priority in pediatric cardiology.

Detecting the Next Epidemic of Congenital Heart Defects

Several of the potential causes of rate increases so far discussed are to some extent predictable. A different concern is the unexpected, unpredictable introduction of a teratogen that could cause an epidemic of congenital heart defects. Known cardiac

teratogens such as retinoic acid and rubella can and have caused clusters of heart defects. Monitoring for the next unknown teratogen-induced “epidemic” of birth defects is a stated goal for many monitoring programs. Effective monitoring has to balance the ability to detect true changes (high sensitivity, low false-negative rates) with the cost of investigating false alarms (false-positive rates). In practice, this requires continuously discriminating among the multitude of signals to identify those with the greatest epidemiologic and biologic plausibility. Setting the bar too high or too low can lead to missed epidemics, either because these are missed altogether (bar too high) or because so many investigations are started with limited resources (bar too low) that some crucial element could be missed.

A typical challenge, for example, is detecting increases of one type of heart defect because of a teratogenic exposure in one part of a country. The often shifting background rates, the challenges of ascertainment, and the limited resources for population-based surveillance make such ongoing monitoring extremely challenging. Rising to these challenges requires increased resources and innovative approaches, some of which are summarized in Table 25.5.

These approaches strive to improve the quality of clinical description and cardiology expertise available to monitoring programs, and to implement a structured, accurate, and rapid response to a concerning “signal.” Particularly in small clusters and when very difficult to otherwise detect, pediatric cardiologists can play an important role as the “astute clinicians,” who note unusual occurrences (e.g., rare defects clustering in time and space) and activate the public health system for further triaging. The subsequent epidemiologic investigations could identify new or emerging causes of congenital heart defects and prevent further epidemics.

Mortality

Preventing congenital heart defects has a significant potential for decreasing infant deaths. Worldwide, congenital heart defects are the leading cause of infant deaths due to congenital

anomalies (57,74). In the United States, population-based estimates using vital records indicate heart defects as the cause of 1 in 24 neonatal deaths overall (4.2%) and 1 in 4 neonatal deaths due to birth defects (24.5%) (75). In Europe, data from Eurocat registries suggests that heart defects also account for approximately 1 in 4 early neonatal deaths to birth defects (36). Among infants <1 year of age, heart defects may contribute to one-third of infant deaths due to congenital anomalies, and, overall, to approximately one-tenth of all infant deaths (57,74). Data from developing countries is scarce, but the early impact of defects is likely even higher than in developed countries, because of the lack of resources to effectively treat babies with severe heart defects. In one study based on WHO data, infant mortality due to birth defects was roughly in inverse proportion to a country’s per capita gross domestic product (74). From a prevention perspective, these findings underscore the global impact that low-cost, effective strategies of primary prevention may have worldwide.

Mortality on a population level can be monitored, readily but with some limitations, using death certificates. Using this approach, researchers have documented how in the United States, mortality from congenital heart defects has been declining for decades (76,77), and by nearly 2% per year from 1979 through 1997 (76). More recent data (78) continues to show a decline in mortality, at an average rate of 3.6% per year in more recent years. Figure 25.7 combines the data from these two studies (76,78), and shows the overall mortality declining from 2.5 to 1 per 100,000 population from 1979 to 2006, an overall 60% decline in 27 years.

Mortality still remains highest in infancy. Throughout the period shown in Figure 25.7, half of all deaths from congenital heart defects occurred before 1 year of life (76,78). Mortality associated with selected heart defects using the most recent United States data is shown in Figure 25.8 (78).

A few types of heart defects accounted for most infant deaths, with hypoplastic left heart syndrome being by far the major contributor. Of note, mortality due to hypoplastic left heart syndrome decreased between 1999 and 2006, whereas this was not as apparent earlier, from 1979 to 1997 (76).

TABLE 25.5 Detecting the Next Epidemic of Heart Defects: Areas for Improvement

Action	Value
Population-based monitoring	Ensures coverage, decreases likelihood of bias (e.g., referral bias)
Clinical description and classification	High-quality description, coding, and classification, based on verbatim descriptions improves accuracy and precision, allows for monitoring of biologically meaningful groups of defects
Clinical collaboration	Pediatric cardiologist collaborating with public health epidemiologist can provide critical clinical expertise to inform and improve monitoring (case review, coding, classification)
Spatial analysis	Improves detection of spatially confined clusters, such as in agricultural areas (pesticides), near hazardous waste sites (contaminants), or in population areas with disadvantaged socioeconomic status (e.g., border areas) Can be added to temporal analysis (time clustering)
National and international networks	Collaborative monitoring and data sharing allows for “alarms” in one area or country to be quickly examined or tested elsewhere. Networks can also share expertise and protocols (e.g., protocols to investigate apparent clusters)
Concurrent monitoring of risk factors	Monitoring of known or putative risk factors can be done on a population level (e.g., rates of diabetes in a province or country) and also individually (screening questionnaires for parents)
Network of astute clinicians	Promotes timeliness and sensitivity: astute clinicians can detect quickly small clusters, generate accurate clinical information, provide clues to exposures, and facilitate contact with affected families for further investigations. Challenge is minimizing unnecessary alarms (false positives)

Figure 25.7. Overall mortality from congenital heart defects (age adjusted), calculated as deaths per 100,000 population in the United States from 1979 to 2006. (Data from Boneva RS, Botto LD, Moore CA, et al. Mortality associated with congenital heart defects in the United States: trends and racial disparities, 1979–1997. *Circulation* 2001;103(19):2376–2381; Gilboa SM, Salemi JL, Nembhard WN, et al. Mortality resulting from congenital heart disease among children and adults in the United States, 1999 to 2006. *Circulation* 2010;122(22):2254–2263.)

Some data are emerging also for *older ages*. In the United States, most deaths after infancy (76%) are occurring in adults rather than in older children (78). The declining mortality among adults and their associated findings were also described by other investigators using the same mortality files (79).

These studies using death certificates provide important data. However, because they are based on death records alone, changes in the underlying birth cohort are not accounted for. For example, mortality (deaths per 100,000 population) could decrease not only when survival improves, but also when birth prevalence decreases, either as an effect of primary prevention or of increased pregnancy termination of affected fetuses. These

situations cannot be distinguished based on death certificates alone. For this reason, these data need to be complemented by occurrence studies. Also, studies that follow a well-defined cohort of people with congenital heart defects over time and assess their outcomes are very important. However, such studies typically are difficult and complex, particularly on a population-basis, but can be feasible in countries with robust population-based health registries and universal health care. Nationwide studies have not been done in the United States. However, with the expansion and linkage of clinical, surgical, and birth defect registries, they might be feasible in the future (80). In Denmark, population-based linkage studies were able to estimate mortality in the entire nationwide cohort of people born with heart defects, from 1977 through 2006 (81). A major finding was this cohort's excess risk of death compared to the general population that extended well beyond childhood. It also documented a declining mortality among adults with several types of congenital heart defects. In Quebec, using linked administrative databases, Canadian investigators were able to evaluate mortality in a population-based group of over 70,000 people with congenital heart defects (82). The study documented gains in survival in all age groups, including adults, but particularly among infants with the more severe types of congenital heart defects (82).

Even if not truly population-based, helpful data can also come from networks of hospitals that cover a large fraction of a country. One such study from Belgium documented the improving survival for specific types of congenital heart defects in children followed by the country's seven pediatric cardiology centers (83); by focusing on one center, investigators were also able to demonstrate improved survival for older birth cohorts (84). In the United States, a few population-based cohort studies have been conducted using state registries of birth defects. One such study, from Texas, assessed survival in a cohort of children with functional single ventricle, including hypoplastic left heart syndrome (85). Aside from documenting variations in survival by type of anatomy and presence of extracardiac malformations, the study also confirmed declining mortality in this complex group of conditions, specifically a 47% decline from 1996 through 2003 (85).

Figure 25.8. Infant mortality from selected congenital heart defects, calculated as deaths per 100,000 livebirths in the United States from 1999 to 2006. (Data from Gilboa SM, Salemi JL, Nembhard WN, et al. Mortality resulting from congenital heart disease among children and adults in the United States, 1999 to 2006. *Circulation* 2010;122(22):2254–2263.)

From a prevention perspective, improving survival is a major goal, ideally through primary prevention, but also through preventing complications and optimizing health in people born with heart defects. Evaluating the effects of prevention will likely require using a combination of epidemiologic approaches. Population-based studies with longitudinal follow up would be of greatest help, particularly, as discussed next, because they would be suited to evaluate not only survival, but also other important outcomes including disabilities, morbidities, and quality of life.

Developmental Disabilities

In estimating the impact of prevention on the life of people with congenital heart defects, it is crucial to include neurodevelopmental outcomes. In one survey, clinicians and parents alike rated neurologic disability a greater concern than cardiac disability when considering quality of life for children with congenital heart defects (86). With improving survival, these outcomes are of increasing relevance and constitute an area of rapidly increasing research (87–89,90,91–96).

Neurodevelopmental outcomes and related clinical issues are discussed in detail elsewhere (see Chapter 73). From an epidemiologic perspective—the focus here—the frequency, range, and causes of neurodevelopmental outcomes associated with congenital heart defects are still incompletely known. Nevertheless, accumulating data suggest the following considerations.

First, neurodevelopmental challenges are common in children with a congenital heart defect who also have an identifiable genetic condition, such as deletion 22q11, or multiple congenital anomalies. In some cases, the genetic condition is undiagnosed at the time of cardiovascular evaluation (97). However, children without syndromes or apparent extracardiac involvement are also at increased risk for adverse neurologic outcomes. Microcephaly, neuronal migration defects and Chiari I malformation have been identified in children with apparently isolated congenital heart defects (98). In some cases, subtle brain anomalies or altered hemodynamics could be present prenatally in fetuses with some heart defects (93,99), as evidenced by small fetal brain volume and signs of impaired brain metabolism on magnetic resonance imaging and spectroscopy (99). After birth, hemodynamics, cyanosis, or the stress and complications of surgery, associated with low birth weight or preterm birth could also play a role (94,97,100–104). It is debated whether children after cardiac transplantation (105) or surgery for single ventricle physiology (100) are at higher risk for adverse neurodevelopmental outcomes.

In general, it appears that in the absence of genetic conditions and severe postnatal complications with brain damage, intellectual disability is probably rare, with overall intelligence typically within the normal range in older children and adolescents. However, deficits in executive function, attention deficit and hyperactivity disorders, and neuropsychiatric conditions such as anxiety and depression could be more common than previously thought. In a systematic review of studies published between 1990 and 2008, Swiss investigators examined 23 studies, including randomized controlled trials, case control, or cohort studies, which evaluated psychological parameters in people with congenital heart defects between 2 and 17 years of age and follow-up of at least 2 years after open heart surgery (106). This review noted the wide range of methodologic quality of the studies, with most studies deemed to be of moderate quality. In their summary of findings, these investigators concluded that according to their parents, a substantial fraction of children experienced psychological maladjustment, particularly in children with

severe heart defects or developmental delay. Nevertheless, studies of long-term psychological adjustment evaluated by self reports tended to indicate good psychological outcomes. The overall conclusion of the review was that a significant fraction of children and young adults who underwent open heart surgery for congenital heart disease (CHD) were at risk for psychological maladjustment but not overt intellectual disability (106).

Such information is useful in planning management and identifying underrecognized issues, such as the need for testing and early intervention. However, with improving prenatal and postnatal management, it is unclear whether what we know now of adolescents and adults, born and treated sometimes decades ago, can be used to counsel the parents of today's babies. For this reason, it is crucial to develop epidemiologically robust, longitudinal studies of developmental outcomes. Studies that follow population-based cohorts would be particularly helpful, as they would capture the entire spectrum of people born with heart defects and would be less prone to biases compared to studies based on one or few referral centers.

Some progress is being made along these lines. In Norway, investigators are utilizing the Norwegian Mother and Child Cohort Study (MoBa), a prospective cohort study conducted by the Norwegian Institute of Public Health, to examine a wide range of outcomes in children with congenital heart defects and their parents. In one such study, investigators linked the cohort of 44,000 children to the Norwegian nationwide heart defect registry. They identified 175 children 3 years of age with congenital heart defects, 60 of whom had severe defects. They then examined the results from maternal questionnaires relative to the child's motor, communication, and social impairment (for this study, investigators used the data collected prospectively at birth, 6, 18, and 36 months). They found that, compared to controls, children with severe heart defects had more than a threefold risk for communication and gross motor impairments, and a twofold increased risk for any developmental impairment. Children with mild and moderate heart defects had a twofold higher risk for gross motor impairment but did not otherwise differ from controls. Of note, impairments were more frequent among children already noted to have developmental delays and a smaller head size at birth (107). The investigators recommended early assessment for motor and communication support provided in children with congenital heart defects, particularly severe types, with the goal of improving long-term outcomes. In a related study (108), investigators from the same group examined whether these same children had a higher risk of internalizing or externalizing emotional problems at 36 months of age compared to controls. They found no evidence of increased risk and speculated this finding could be related to the fact that these children had completed the bulk of their medical and surgical treatment (108). These studies are notable not only for their methodologic strength and results, but also as an example of a systematic, large-scale approach to evaluating health and outcomes over the lifespan. Its ongoing design will hopefully continue to generate additional outcome data on older children and young adults.

In summary, some children with congenital heart defects appear to be at risk for adverse development and psychological outcomes, although their frequency, magnitude of risk, and predictors have not been clearly defined. The impact of these outcomes in terms of use of services, cost, disability, and quality of life for patient and family has not been formally evaluated. Incorporating these outcomes into the "cost" of congenital heart defects would provide a more realistic evaluation of the potential benefits of primary prevention, and a further incentive for research and preventive interventions.

Quality of Life

Health-related quality of life is a focus of increasing interest in pediatric cardiology. By definition, quality of life is a multidimensional construct that integrates an individual's subjective perception of physical, social, emotional, and cognitive functioning. This definition highlights the construct's major strength, namely, bringing to the forefront the subjective perspective of the person with a congenital heart defect (and the family). The need for long-term studies of quality of life is increasingly recognized (90,109). Such studies also try to incorporate dimensions, often missed by other approaches, such as school functioning, social functioning, independent living, and social integration (88). Because such perspectives are not retrievable from clinic and administrative records, quality of life studies require new skill sets as well as novel methods and tools (110–113). In fact, a major challenge has been the scarcity of validated assessment tools targeted at people with congenital heart defects and their families. Because of this, many studies are difficult to compare and summarize: a recent review found that in 12 studies of quality of life studies in people with congenital heart defects (106), eight different assessment tools were used, and only three were used in more than one study. Having common validated tools will help speed progress in this field. With these limitations in mind, it is not surprising that current findings are often inconsistent, as may also be expected for an outcome that depends on a web of factors, including disease severity, surgery, health care support, family support, insurance coverage, income, and societal attitudes toward chronic illness (90,114–118).

For example, one population-based study in Finland found reasonably good outcomes in a group of people with congenital heart defects (mainly mild-to-moderate conditions such as septal defects), including educational attainment, employment level, and frequency of steady relationship (119). By contrast, several studies in North America and Europe reported worse health-related quality of life in people with congenital heart defects compared to reference groups (120–123). Such outcomes in some studies appeared to vary by anatomic lesion and surgeries (116,124), family income (114), and age (125–127). Also, obtaining employment, health insurance, and mortgages were noted as challenges in the United States (128), even for people with mild heart defects (129).

These data should be viewed as exploratory and preliminary, given the heterogeneity in methods and results across studies. A recent systematic review (106) found that in four of the 12 studies analyzed, quality of life of selected congenital heart defects (not always the same across the different studies) was comparable to normative samples according to proxy- (130,131), self- (132) or combined reports (133). One study even observed a better self-reported quality of life compared to healthy norms in a large sample of children with transposition of the great arteries undergoing surgery (116). In contrast, four studies reported an impaired quality of life in many self- and most proxy-reported dimensions (114,120,134,135). Two studies compared quality of life of children with congenital heart defects with that of children with other chronic illnesses: one study found better proxy-reported quality of life among children with congenital heart defects (135), whereas the other study found the converse (131). However, these studies are difficult to compare because they used different tools that tended to measure different dimensions of quality of life (106).

Some studies have tried to identify clinical predictors of quality of life, with inconsistent results. For example, a poorer quality of life was associated only in a minority of studies with the complexity of heart defects, type of surgery, duration of circulatory arrest, and number of surgical procedures (106). In two studies, a poorer quality of life was observed with postoperative complications, length of hospital stay, and current

need for cardiac medication (114,134). Factors that influenced parental quality of life in at least one study included being unemployed or having a low income because of the child's health condition (114), the presence of an adverse family relationship (114), and parental stress at follow up (136). Finally, in two studies, older age at follow-up assessment was associated with a better quality of life (120,135).

In summary, even with incomplete and heterogeneous data, it appears that the quality of life in children and young adults with congenital heart defects seem to be affected, more so when assessed by parental reports than self reports. Also, parent's quality of life appears affected, perhaps even to a higher degree than in their children. The implication for management is that support needs to be aimed not only at the child but also at parents, ideally in an integrated approach. Looking at the future, although the evidence base relative to quality of life is still less than robust, research in this area is expanding rapidly. Specific tools for people with heart defects are being developed and validated, including a cardiac module for the PedsQL (123,137) currently undergoing validation, and a disease-specific Pediatric Cardiac Quality of Life Inventory (138,139) with patient and parent-proxy forms and adapted for a wide age range. These developments should lead to a more extensive and robust body of literature that could be very helpful not only in delivering optimal clinical care but also in providing a more realistic assessment of benefits of prevention that incorporates the quality of life of people with congenital heart defects and their families.

Health Disparities

Health disparities are a primary consideration in implementing and evaluating prevention activities (140). Disparities typically refer to differences in the occurrence, mortality, and burden of disease among groups of people. Disparities may arise because of the unequal distribution in the population of risk factors, including access to care, environmental exposures, low socioeconomic status, compounded or heightened by variations in disease susceptibility (140,141). Identifying and eradicating health disparities are critical steps in pursuing a measure of social justice in community health (140,141).

One example of health disparity is the disproportionate mortality for congenital heart defects (and birth defects in general) in developing countries compared to developed countries, as discussed above. However, health disparities appear also within developed countries, and are a major concern (140). For example, mortality for congenital heart defects in the United States, appears to vary by race and ethnicity and this has been documented for decades (76,78). As illustrated by Figure 25.9, infant mortality in the US, based on death certificate files through 2006, has been consistently higher from black infants than for white infants (78). For Hispanic infants, the pattern is less consistent, and rates are closer to those in white infants than reported previously (76,77).

The potential complexities of these evaluations are highlighted in a recent report on neonatal mortality associated with congenital heart defects in the United States (75). Using vital record data, investigators reported similar overall neonatal mortality between black and white infants. However, these findings changed considerably when stratified by gestational age. For example, among term infants, the neonatal mortality attributable to heart defects was 20% higher among infants of black mothers compared with white mothers, but among preterm infants, the rate was 30% lower among infants of black mothers compared to white mothers (75).

These differences in outcomes by race and ethnicity have been documented independently using different approaches, including follow-up studies after surgery for congenital heart defects using inpatient databases (142) and a population-based

Figure 25.9. Infant mortality from selected congenital heart defects by race-ethnicity, calculated as deaths per 100,000 livebirths in the United States from 1999 to 2006. (Data from Gilboa SM, Salemi JL, Nembhard WN, et al. Mortality resulting from congenital heart disease among children and adults in the United States, 1999 to 2006. *Circulation* 2010;122(22):2254–2263.)

studies of early childhood mortality (143). The latter study identified an approximately twofold higher risk of dying in non-Hispanic black infants with selected severe heart defects compared to white infants, and smaller increased risk for Hispanic infants (143).

Expanding the assessment of potential health disparities over the lifespan (Fig. 25.10), researchers have examined United States death certificate data looking at race-specific mortality by age group (78).

Mortality in blacks compared to whites was disproportionately higher in infants and children (rate ratios of ~1.5 overall), continued to be higher but less so through age 35 years, and became similar or even lower in older adults (perhaps because of fewer survivors or fewer diagnoses at those ages). For Hispanics, the pattern is less consistent, with higher mortality than whites in very young children, but similar and even lower mortality than whites in older age groups. The reasons behind these differences are still unclear (75), and further studies are needed to understand whether they are due to reporting, prenatal diagnosis, prevalence of heart defects, or to differences in risk factors for congenital heart defects or medical treatment.

In general, by reducing occurrence, primary prevention ought to ameliorate such disparities. A mix of targeted and population-based interventions is probably required to ensure that the benefits of prevention accrue equally to all segments of the population. This is particularly important for interventions aimed at exposures that affect the population unequally, such as maternal diabetes, smoking, or lack of preconceptional care. Similar considerations apply also to interventions aimed at improving outcomes among people with heart defects (secondary prevention).

Cost

Cost can be a powerful incentive for prevention. Current cost estimates are particularly important when projecting the future benefits of prevention and comparing these with the investments needed now to make prevention happen (144).

Figure 25.10. Rate ratios comparing mortality from congenital heart defects by race-ethnicity (non-Hispanic black vs. non-Hispanic white, Hispanic vs. non-Hispanic white) in different age groups in the United States from 1999–2006. Lines represent 95% confidence intervals. Rate ratios above 1 suggest increased mortality, and rate ratios below 1 suggest decreased mortality compared to the reference group (non-Hispanic white). (Data from Gilboa SM, Salemi JL, Nembhard WN, et al. Mortality resulting from congenital heart disease among children and adults in the United States, 1999 to 2006. *Circulation* 2010;122(22):2254–2263.)

However, current cost estimates of congenital heart defects in the United States are far from being precise, complete, or timely. Part of the reason lies in the complexity of cost estimation, but a significant part lies also in the fragmentary nature of health care, restricted access to data, and incompleteness of many databases with health expenditure information. Before reviewing the literature on cost estimate, it is helpful to briefly outline the main elements of cost and the related data sources. Further information is available with extensive references in a recent review (144).

COMPONENTS OF COST

To understand the basic aspects of cost, it can be helpful to imagine following a cohort of people with heart defects from birth (or ideally pregnancy) through the lifespan. The cost of congenital heart defects, from a societal perspective, can be defined broadly as the consumption of resources in producing a good outcome, that is, optimal health, in this cohort. (Usually one is interested in incremental cost, which is the cost over and above the cost of people without heart defects). With primary prevention, these incremental costs should be saved. With secondary prevention, which is aimed at improving outcomes through optimal care of people with heart defects, some costs will be saved by preventing complications, whereas others might increase because of prolonged care with longer survival; better cost-effectiveness, if not cost saving, would be the goal.

Viewed as consumption of resources, the cumulative cost of congenital heart defects over the lifespan will have several components, some of which are easier to assess directly, whereas others may require more assumptions and complex statistical modeling. The obvious and most tangible component of cost is the direct medical cost, that is, the health expenditures for providing medical care and other services to people with congenital heart defects. These would include not only inpatient costs (facility as well as professional services costs), but also outpatient costs (office visits, emergency room visits, rehabilitation and early interventions services, etc.) and pharmacy costs. Additional components from a societal perspective are the so-called indirect costs. These include mainly the reduced economic productivity for people with congenital heart defects. Caregiver costs, including lost productivity of caregivers as their activity are diverted to the care of affected family members, are important but rarely incorporated formally into cost estimates.

GOALS OF COST ESTIMATION

Ideally, in estimating cost in a prospective cohort of people with congenital heart defects, several metrics would be derived: incremental cost (rather than charges) due to heart defects, in the aggregate cohort as well in groups of people with specific types of heart defect; direct and indirect costs, separately and combined; cost breakdown by age group as well as longitudinally over the lifespan; national cost; and costs on a yearly basis. These data would be especially valuable if monitored in a timely manner and derived from a population-based, representative cohort of people with congenital heart defects that are accurately diagnosed and well characterized. Having this ideal situation in mind is helpful when evaluating the cost information currently available, which typically lacks several of these attributes. The overall result is that available cost studies likely underestimate, probably by a large margin, the true cost of congenital heart defects. In doing so, they also underestimate the potential benefits of prevention.

ESTIMATING COSTS

In the United States, several health expenditure databases have been used by researchers to estimate cost (144). Some are commercial databases. The MarketScan Commercial Claims

and Encounters database, for example, contains considerable cost information on inpatient admissions and outpatient services. However, this database covers a select population of employees of a set of large self-insured corporations, and is not representative of the general population. Also, researchers are not currently allowed to link these data to outside heart defect registries; to identify and characterize people with congenital heart defects, researchers need to use the ICD codes in the MarketScan database, with well-known problems of miscoding leading to false-positive and false-negative diagnoses. Another resource for cost estimation is the Healthcare Cost and Utilization Project (HCUP), which provides two nationally representative databases: the Nationwide Inpatient Sample (NIS), based on a 20% sample of community-based hospitals, and the Kids Inpatient Database, focusing on pediatric admissions, estimated to cover about 90% of births in the United States. These databases, however, cover only inpatient admissions, and even for these, they include facility costs but no professional service fees, which can be considerable in children with heart defects. Also, no outpatient services are included. Medicaid is a third resource used for cost estimates. It contains comprehensive data, can be linked to birth defect registries, but includes only patients covered by Medicaid and varies in operation between states, limiting extrapolations to the national context.

In summary, in the United States, fairly extensive cost information is typically available only on select, typically nonrepresentative cohorts of people, whose diagnosis is difficult to validate. Conversely, for nationally representative samples only partial cost information, consisting typically of some part of direct medical costs such as inpatient admissions, typically can be obtained. Also, nearly all these data are cross-sectional, rather than longitudinal. With these strengths and limitations in mind, one can now focus on two important metrics of costs for which some data are available, namely, cross-sectional costs and lifetime costs.

CROSS-SECTIONAL COSTS (ANNUAL COSTS)

A helpful estimate for health care professionals and policy makers is the cost of congenital heart defects in a population, in any given year. By providing a cross section of costs in one point in time, these estimates can indicate the immediate short-term cost savings potentially deriving from prevention, particularly primary prevention. Nationally representative estimates of costs (rather than charges) have been produced for people with major congenital heart defects in the aggregate and for specific defects, using the HCUP database (HCUPnet) (144,145). According to these data (Fig. 25.11), the estimated cost of inpatient admissions alone in 2004 for people with congenital heart defects, all ages, was \$1.4 billion.

People with congenital heart defects were identified by ICD codes (745.0 to 747.9) in the principal discharge diagnoses. As high as this figure seems, it still likely underestimates the inpatient cost because, for example, professional services fees during the admission are not included. Nevertheless, it is an important aggregate estimate. An expanded assessment of this dataset (144) provided an additional estimate associated with a subset of severe heart defects. These were defined, based on ICD codes alone, mainly as conotruncal, single ventricle, hypoplastic left heart syndrome, Ebstein anomaly, and endocardial cushion defects. The associated cost, for the same year, and across all age group, was \$511 million (Fig. 25.11). Nearly all admissions for these defects were among infants (95%). However, the study authors noted that admission for heart-defect related causes in older patients could be less likely to be assigned congenital heart defect codes compared to younger patients, leading to an underestimate of costs among adults.

To try and capture not only inpatient admission costs but also outpatient costs, the same investigators also conducted an

Figure 25.11. Estimated nationwide costs for inpatient admissions for congenital heart defects, overall and in a subset of severe heart defects in the United States in 2004. (Data from Boulet S, Grosse SC, Riehle-Colarusso T, et al. Health care costs of congenital heart defects. In: Wyszynski DF, Correa-Villasenor A, Graham TP, eds. *Congenital Heart Defects: from Origin to Treatment*. New York, NY: Oxford University Press, 2010:493–501; Russo CA, Elixhauser A. Hospitalizations for birth defects, 2004. In: HCUP Statistical Briefs. Rockville MD: U.S. Agency for Healthcare Research and Quality; 2007.)

analysis of MarketScan data (144), focusing on costs for the 2005 for children 0 to 3 years of age with a major congenital heart defect (Fig. 25.12).

The mean cost among infants was estimated at nearly \$100,000 among infants, or 25 times the cost for children without a congenital heart defect (cost ratio). The costs decreased by about one-third among 1-year-olds and again among 2-year-olds, with cost ratios of 12 and 9, respectively. The mean costs were over four times the median costs, indicating that some children contributed disproportionately to the costs. Figure 25.12 also shows the costs associated with by severity. Children with the more complex heart defects were one-tenth of all children with heart defects in the study (153/1,530) but contributed disproportionately to overall costs (Fig. 25.12).

Figure 25.12. Estimated cost (inpatient admission and outpatient services) for 2005 in a select United States population of children under 3 years of age with congenital heart defects. (MarketScan data from reference Boulet S, Grosse SC, Riehle-Colarusso T, et al. Health care costs of congenital heart defects. In: Wyszynski DF, Correa-Villasenor A, Graham TP, eds. *Congenital Heart Defects: from Origin to Treatment*. New York, NY: Oxford University Press, 2010:493–501.)

As noted by its authors (144), this study using MarketScan data has some limitations. The database covers a select, privately insured population, so findings are difficult to generalize. Also, it doesn't capture the switch of some children to state funded programs, such as Medicaid, when costs reach the lifetime limits or parents cannot afford private insurance any longer. Finally, as in other studies without clinical validation, ICD codes may be inaccurate and some cases may have been misclassified. Nevertheless, with its limitations, this is an important study. It examined health expenditures associated with inpatient admissions as well as outpatient and pharmacy services, included a wide variety of congenital heart defects, and assessed the cost variations by age in early childhood and, to the extent possible for ICD codes, also by disease severity.

The cost among adults is unclear and very likely underestimated. One study used the NIS dataset to examine inpatient costs in adults (18 years or older) with a select group of complex congenital heart defects (146). For 2002, a total of 28,072 hospitalizations were identified for adults with these conditions (mean age, 50.8 years), with a mean charge (not cost) per patient of \$31,740. However, the true costs could be higher, as discussed, because ICD codes for congenital heart defects may be underused in older people.

LIFETIME COSTS

Lifetime costs aggregate the costs accumulated by people with congenital heart defects as they progress through life. Ideally, they include not only direct but also indirect costs such as loss of productivity. From a societal perspective, comprehensive lifetime costs are crucial metrics. From a prevention perspective, these lifetime costs provide comprehensive economic estimates of the potential “return on investment” for prevention. For example, the “return on investment” of preventing diabetes-related congenital heart defects in pregnancies occurring in 1 year is the savings gained by not having to expend resources that would have been consumed by affected babies born in 1 year *over their lifetimes*. These lifetime costs, however, are currently complicated to estimate and require assumptions and modeling.

A comprehensive lifetime cost estimate for selected congenital heart defects was reported in a landmark study in the mid-1990s (147,148). In the study, researchers linked the California birth defect registry with health expenditure data and used sophisticated methodology to estimate lifetime cost of illness for babies born each year with four major heart defects. The findings were then extrapolated to the population of the United States at that time. The estimated lifetime cost per *individual new case* is shown in Figure 25.13.

These total costs per case ranged from \$262,000 for tetralogy of Fallot to over \$500,000 for truncus arteriosus. These estimates represent incremental costs for babies born in a single calendar year (1988) with one of the four heart defects, projected through their lifespan. They include not only direct costs (medical, developmental, and special education services) but also some indirect costs (costs of lost work and household productivity). Because these were incremental costs, the cost for general population was subtracted out. Finally, the dollar figure was based on 1992 dollars, obviously a gross underestimate compared to today.

A helpful estimate for national policy is that of total aggregate costs for the nation. These are shown in Figure 25.14, using similar sources and methodology (147,148).

As Figure 25.14 indicates, lifetime costs in the national aggregate are measured in millions of dollars for a single-year cohort, with a combined cost for the four conditions exceeding 1.2 billion in 1992 dollars. A large fraction of these costs were indirect costs, due to loss of productivity because of high early mortality. However, direct medical costs were in the order of 500 million dollars, mainly related to surgical care (147,148).

Figure 25.13. Estimated lifetime costs (total costs) per new case, for four major congenital heart defects, in 1992 dollars. (Data from Centers for Disease Control and Prevention, Waitzman NJ, Romano PS, Scheffler RM, Harris JA. Economic Costs of Birth Defects and Cerebral Palsy—United States, 1992. *MMWR Morb Mortal Wkly Rep* 1995;44: 694–699.)

Comparing cost per case (Fig. 25.13) and cost for the national cohort (Fig. 25.14) for the four defects, underscores the impact of birth prevalence on cost. For example, the cost associated with each new case of truncus arteriosus is nearly twice that for d-transposition complex, but the aggregate costs in the United States for truncus arteriosus are less than half that of d-transposition. This is due to the fact (Table 25.3) that the birth prevalence of d-transposition is about four times that of truncus arteriosus, thus driving up the aggregate costs in the population.

In summary, the costs of congenital heart defects are high and increasing. However, the true nationwide cost is difficult to estimate in the United States because of the fragmentation of data and health care and the complexity of how health care

Figure 25.14. Estimated lifetime costs (total costs and medical costs) in 1992 dollars for the cohort of people born in 1 year (1988) in the United States with one of four major congenital heart defects. (Data from Centers for Disease Control and Prevention, Waitzman NJ, Romano PS, Scheffler RM, Harris JA. Economic Costs of Birth Defects and Cerebral Palsy—United States, 1992. *MMWR Morb Mortal Wkly Rep* 1995;44: 694–699.)

is paid. In other countries with national health care systems and comprehensive databases, such costs could be more easily estimated. Nevertheless, even the most basic and conservative costs estimates based on 1 year inpatient care of a decade ago surpass the billion dollar mark. The real costs today are likely even higher, for several reasons: estimates of lifetime costs to date capture only a small fraction of congenital heart defects; medical costs have risen over time; survival has improved, so costs now accrue for more people over a longer period of time; and some components of costs are rarely estimated, including time spent and loss of productivity by family members and costs related to neurodevelopmental disabilities (144,147,148).

Accurate estimates and timely monitoring of costs are crucial in providing services and particularly as an incentive for investing in prevention. As an example, preventing a single case of d-transposition of the great arteries through preconceptional treatment of a diabetic woman would save at least 277,000 dollars (in 1992 United States dollars). These figures should provide powerful financial incentives to invest in preventive services for women of childbearing age (147,148), particularly in times of soaring costs and increasingly limited resources.

EVIDENCE: EPIDEMIOLOGY OF RISK AND CAUSES

The starting point for effective primary prevention is identifying true modifiable causes of congenital heart defects in human populations. Several risk factors, such as diabetes or retinoic acid, reach this level of evidence and are prime candidates for prevention efforts. Others are less well characterized. Causality may be in question (e.g., obesity) or the magnitude of risk may be unclear (e.g., lithium), typically because of inconsistent findings across studies or concerns about bias and confounding.

Part of the challenge of characterizing risk factors has been the near-exclusive reliance on observational studies. For most maternal and environmental factors, randomized clinical trials are out of the question. Exceptions may include factors that are potentially protective, such as folic acid supplementation, where risk reduction is expected and no material side effects are anticipated. But for most other factors, randomization is unethical and even unfeasible (e.g., maternal diabetes). Thus, one is typically left with observational studies, typically case-control studies, and occasionally cohort studies. Because of their complexities, observational studies are seldom consistent and the resulting steady stream of epidemiologic findings may appear disappointingly confusing and difficult to interpret. For this reason, before examining individual risk factors, it is helpful to review some key epidemiologic concepts in risk assessment. These concepts can provide a framework for navigating the complex and ever increasing body of epidemiologic studies on the etiology of congenital heart defects (3,149).

Evaluating Risk Through Epidemiology: Application to Heart Defects

From the perspective of prevention, that is, in order to develop policies and strategies, a risk factor needs to be comprehensively characterized. Some of the important elements in this process are summarized in Table 25.6.

The first element, causality, is perhaps the most challenging. Observational studies typically generate associations. Moving from associations to causality is not simple: causality is a complex concept that requires thoughtful evaluation (150) together with evidential support that goes beyond the

TABLE 25.6 Characterizing Risk Factors: Questions and Epidemiologic Correlates

Questions	Epidemiologic Correlates
Causality: does the factor cause heart defects?	Causality is inferred by finding consistent, plausible associations in multiple, well-designed epidemiologic studies, ideally population based, while controlling for bias and confounding.
Specificity: what types of heart defects does the factor cause?	Establishing specificity requires typically large samples of well-characterized cases of types of heart defects: this implies large, collaborative studies (for sample size) and clinician involvement (for accurate case classification).
Magnitude: how strong is the risk for heart defects?	Magnitude is measured by a study's risk estimates. Relative risk (ratio of disease rate exposed/disease rate in unexposed) can be estimated by cohort and case-control studies; absolute risk (risk of disease when exposed) is readily estimated in cohort studies (can be inferred in population-based case control studies augmented with some external information).
Interactions: what is the risk when exposed to more than one factor?	Interactions may occur between multiple environmental exposures (diabetic women who smoke and drink) or between environmental exposures and genotypes (e.g., MTHFR polymorphisms and folate supplementation). Risks may be combined in an additive, multiplicative, or other scale. Methods are available to determine interactions, but typically require larger, very well designed studies.
Population attributable fraction: what fraction of heart defects in a population is attributable to the factor?	Population attributable risk depends on both the magnitude of risk (relative risk) and the frequency of the factor in the population. The latter can be inferred from surveys, or, in some cases, from the control sample of population-based case control studies. Crude estimates of attributable fraction may be computed easily, but accurate estimations require thoughtful analyses.

results of a single study, however well-conducted. For observational studies, the case for causality can be strengthened by consistent, plausible associations from multiple well-designed studies that stringently control for confounding and convincingly minimize bias. Confounding and bias are significant concerns. For example, an association between maternal smoking and congenital heart defects could be due to confounding by alcohol use, if alcohol causes congenital heart defects and is more common among smokers compared to nonsmokers. The same association could also be spurious because of bias; for example, recall bias can occur in a case control study if mothers of affected babies are more likely than mothers of controls to remember or report smoking during pregnancy. Biases may also hide associations. For example, associations could also be diluted or distorted if exposures are not assigned correctly, as can happen when exposure assessment relies on maternal reports (for smoking but also many factors such as fever, chronic illnesses, medication use) with limited validation or use of biomarkers. Finally, in addition to confounding and bias, associations may be due to also chance. In the case of smoking, this can occur if the excess of smokers among case-mothers in a case-control study is randomly due to sampling. The effect of chance is important but fairly easy to measure and manage, whereas confounding and bias can be difficult to prevent, detect, and eliminate. Specificity (Table 25.6) is important for several reasons. A consistent association can provide clues to pathogenesis and strengthen the case for causality, as in the case of retinoic acid as a specific and consistent cause of complex conotruncal defects, probably through a developmental effect on neural crest cells. However, specificity is not always present, and established teratogens such as maternal diabetes can cause a variety of heart defects. Identifying associations with a specific effect on selected heart defects requires considerable care in study design and ideally the collaboration of expert clinicians in case review and classification. From a prevention perspective, specificity also helps

assess the potential benefits for prevention—a factor causing hypoplastic left heart syndrome would be viewed differently from one causing a small atrial septal defect.

Magnitude of risk can be estimated in case-control and cohort studies, in the form of relative risk of disease, that is, the ratio of disease risk in the exposed divided by the risk in the unexposed. Some relative risks may be low (e.g., smoking), others can be considerable (maternal diabetes), and a few can be extremely elevated (e.g., retinoic acid). Ideally, one would also estimate the absolute risk for congenital heart defects, that is, the absolute rate of disease in those exposed (the numerator of relative risk). This is important information in individual counseling. The relative risk for a specific type of congenital heart defect could be 10 (i.e., 10 times the risk in the unexposed), but if the baseline risk in the unexposed is low, say 1 in 10,000, then the absolute risk, though increased, is still in the order of 1 in 1,000 (or 999 to 1 odds of *not* developing the heart defect).

Interactions (Table 25.6) are potentially important but challenging to identify and characterize precisely. An interaction occurs when the concurrent presence of two factors changes the risk association between each factor alone and disease. These factors can be environmental or genetic. For example, a scenario may occur (not as implausibly as may appear) in which a diabetic woman takes lithium and a folic acid supplement. The question then becomes if and how these individual risks cumulate, and if they do, on which scale (additive, multiplicative, or other). The answers are not just of academic interest. Finding that a vitamin supplement mitigates the risk associated with diabetes or lithium can provide a powerful adjunct tool in clinical management. Also, strong interactions can provide clues to shared pathogenesis and help discover new causes and mechanisms of congenital heart defects. The methodologic challenge, however, is that studying interactions requires stringent precision in assigning exposure and usually much larger sample sizes compared to studies looking at the main effects of risk factors.

Finally, the population attributable fraction (Table 25.6) is particularly helpful in translating measures such as relative risk into estimates of population impact—the number of cases caused by the risk factors. It is intuitive that the more women exposed to a teratogen in a population and the higher the teratogenic risk, the higher the number of affected pregnancies. The population attributable fraction develops this notion rigorously. It is defined as the proportion of cases in a population that can be attributed to a given exposure and is computed as a nonlinear function of disease risk and exposure prevalence, using one of several formulas (151,152). Figure 25.15 illustrates the relation between exposure frequency, disease risk, and population attributable fraction, using a range of plausible values for common risk factors.

This illustration underscores several basic concepts. First, the higher the frequency of exposure to a risk factor, the higher the fraction of cases in the population that is attributable to that factor. The attributable fraction increases as a nonlinear function of the relative risk—the higher the relative risk, the steeper the increase. However, even weak risk factors, with odds ratios of 1.5 to 2, can potentially cause a significant fraction of disease in the population with sufficiently high exposure frequencies. High exposure frequencies are not unrealistic: lack of folic acid supplementation easily exceeds 50% in many developed countries and is probably close to 100% in many developing countries. Smoking rates of 15% to 20% or more in women are not uncommon in some countries or groups in the population.

Whereas attributable fraction may appear to be a straightforward concept (151), in many practical settings it has subtleties that must be appreciated in order to get valid estimates. Such settings include using relative risk estimates derived from multivariable analyses, a common situation in modern epidemiologic studies, or when the exposure has more than two levels rather than being categorized simply as present or absent (153,154). With rare exceptions (155), a systematic assessment of population attributable risk for heart defects has been uncommon. Because of its potential implications for prevention, new rigorous evaluations would be very helpful.

Seeking Candidates for Prevention: Review of Selected Risk Factors

Because of the focus on primary prevention, this review will center on selected modifiable risk factors (Table 25.7), chosen either because they are established risk factors for congenital heart defects (e.g., diabetes, retinoic acid) or because they are so common in many populations (e.g., smoking, obesity) that they should be addressed even if associated with only mildly increased risks for congenital heart defects. The examination of these risk factors is not exhaustive; rather, it focuses on specific aspects relevant to primary prevention, such as the strength of the evidence, the specific outcomes related to the factor, the preventability of the risk factor, and its frequency in the population. Additional data can be found in several reviews (3,149) as well as in the cited primary sources. Because of the continuous stream of studies, the information is to some extent always provisional. Helpful sources for updates, in addition to the published literature, include online databases such as Reprotox and TERIS (156,157), as well as the staff at Teratogen Information Services (TIS) who can provide invaluable summaries and commentary (158,159).

Diabetes

Maternal diabetes is a well-known and established teratogen. It causes heart defects not uncommonly as part of multiple congenital anomaly patterns (16,160–168). Cardiac phenotypes consistently associated with maternal diabetes include laterality defects (heterotaxy) and several conotruncal defects. Less consistently, but still associated with maternal diabetes are left ventricular outflow obstructive defects and septal defects (16,160–164,167,169). Obstructive cardiomyopathy also occurs but typically resolves over time. Estimated relative risks for heart defects in the aggregate range approximately from 3 to 6, though they can be higher for some types of heart defects, especially when associated with extracardiac anomalies (16,160,161,163,164,166,167). Separate risk estimates associated with type 1 and type 2 diabetes are rarely

Figure 25.15. Population attributable fraction as a function of relative risk and population exposure frequency, with selected examples of common exposures (see text for details).

TABLE 25.7

Common Exposures Associated with Increased Risk for Congenital Heart Defects: Estimated Effects, Risk, and Prevention

Factor	Congenital Heart Defect	Estimated Risk	Exposure Type and Frequency	Comments
Diabetes	Early developmental CHDs, that is, laterality defects, looping, conotruncal defects, AV septal defects	OR usually 3–10, higher for some phenotypes	Pregestational diabetes	1%–2% of women of childbearing age in United States; increasing in many countries
Febrile illness, influenza	LVOTO, including coarctation of the aorta; tricuspid atresia, dTGA and other conotruncal malformations, VSD, possibly others.	For febrile illness, relative risk between 1.5 and 3 (generally –2), thought possibly higher for tricuspid atresia. For influenza, similar risk estimates	First trimester febrile illness reported in ~6%–9% of pregnancies. Generally associated with respiratory or flu-like symptoms.	Relative contribution of hyperthermia and underlying infection unclear. Risk may be higher when influenza-like illness is associated with high fever.
Maternal phenylketonuria	Tetralogy of Fallot, VSD, PDA, LVOTO	Relative risk up to 6	Frequency of PKU is ~1 in 10,000 among whites	Known teratogen. Relatively rare, but effects preventable with strict dietary compliance from before conception
Retinoic acid	Conotruncal defects	High absolute risk	Isotretinoin, etretinate by mouth are teratogenic, topical tretinoin probably not	Retinoic acid use is subject to rigorous controls in some countries but not others. Exposure is a concern because many users are young women
Lithium	Ebstein anomaly, others	Relative risk likely <10, between 1.5 and 8 in two cohort studies	Use probably infrequent but few systematic studies	Risk lower than originally thought, but likely present. Balance of risk versus benefits of treatments need to be considered.
Obesity	Several heart defects, including conotruncal defects, unclear if specific	Relative risk between one and three, but some studies are negative. Causality not clear	Risks typically associated with BMI > 29, but some studies show risks at BMI 25–29	Causality not clear. Association possibly owing in part to unrecognized diabetes. Important individual and public health concern, as obesity is increasing in many countries
Smoking	Septal defects, others	Relative risk between one and three, but some studies are negative. Causality not clear	In individual studies, risk present if both parents smoke and if father alone smokes (second-hand smoking)	Causality not clear, but preventable. Smoking can cause other adverse pregnancy outcomes
Caffeine	No clear association with structural CHDs	No clear association has been demonstrated	No clear increased risk, no trend for increased risk with increasing amount of caffeine	Caffeine crosses the placenta and can have cardiovascular effects. However, several large studies failed to identify increased risk for heart defects or other malformations
Alcohol	Possibly several heart defects, including conotruncal defects	Inconsistent findings; some studies do not find association	Possible higher risk with high exposure, but not consistent finding	Known teratogen, major effects on central nervous system, association with specific heart defects still being investigated

AV, atrioventricular; OR, odds ratio; LVOTO, left ventricular outflow tract obstruction; dTGA, d-transposition of the great arteries; VSD, ventricular septal defect; PDA, patent ductus arteriosus; BMI, body mass index; CHDs, congenital heart diseases.

available. Some studies have suggested an excess risk also with gestational diabetes, but the literature is inconsistent (162,170–172).

The frequency of diabetes among women of childbearing age varies by country, age, and other factors. According to one estimate, diabetes affects approximately 2% or 1.85 million women of childbearing age in the United States, and preconceptional diabetes management could decrease the risk for pregnancy loss and congenital malformation for approximately 113,000 births per year (141). Rates of diabetes are not only high, but rising in both developed and developing countries (173,174). Of additional concern is that many women could have unrecognized diabetes. One study estimates that in the United States, for every two women of childbearing age diagnosed with diabetes, there is another one with undiagnosed diabetes (175).

Even without considering the overall effect on women's health, these three elements—strong evidence for causation, high relative risk for disease, and comparatively high and rising frequency in the population—combine to make diabetes a clear priority for prevention. Of major importance is therefore the finding that careful metabolic control before conception can reduce considerably the teratogenic risk associated with maternal diabetes (141,176,177). In practice, however, many affected pregnancies continue to occur (141,166,178), highlighting the challenges of implementing optimal preconceptional control (179).

Some findings suggest that birth defect risk may be lower among diabetic women who also took a folic acid-containing multivitamin supplement from before conception (161). If confirmed, taking such a supplement could represent an adjunct prevention strategy for diabetes-associated birth defects. This benefit would add to the established benefit of folic acid in preventing neural tube defects. In summary, maternal diabetes is an established, serious risk for congenital heart defects, and a clear priority target for prevention efforts.

Rubella

The teratogenicity of rubella in pregnancy is well-established. The effectiveness of rubella immunization in decreasing rubella-associated birth defects is testimony to the power of primary prevention worldwide (180–182). Specific heart defects associated with congenital rubella syndrome include pulmonary stenosis, particularly branch pulmonary stenosis (180), patent ductus arteriosus, and, less frequently, other conditions such as tetralogy of Fallot (183).

Through sustained immunization campaigns, congenital rubella syndrome has been nearly eliminated in the United States and some other countries, though continued vigilance is crucial because of lapses in immunization coverage, imported infection, and the challenges of surveillance (182,183). Worldwide, rubella infection and congenital rubella syndrome remain a significant problem, underscoring the need for global eradication of this preventable condition (182,184,185).

Fever and Flu

Fever and hyperthermia are established teratogens in animal models (186–188). However, the extent of cardiac teratogenicity of fever and flu-like illnesses in humans is unclear. The evaluation is made challenging also because reports of febrile illness in pregnancy are difficult to validate, and because the association could be confounded by the underlying infection or use of medications. The balance of the evidence to date suggests that first-trimester febrile or flu-like illnesses are associated with a moderately increased risk for congenital heart defects in the aggregate (relative risks of approximately 1.5 to 3), with perhaps higher relative risks for some right-sided obstructive defects, coarctation of the aorta, aortic stenosis,

ventricular septal defects, and atrioventricular septal defects in children with Down syndrome (18,164,187,189–192). However, these findings are inconsistent across studies.

Data on the frequency in the general population of fever and flu-like illnesses in early pregnancy are difficult to find in national surveys. However, judging by the prevalence among controls in case-control studies (which should represent the underlying population), it appears that approximately 6% to 9% of women experience a respiratory infection (“flu”) or a febrile illness during the first trimester of pregnancy (18,189–191). If this is true, an estimated 250,000 pregnancies or more could be exposed every year in the United States.

If febrile illnesses cause congenital heart defects, prevention strategies may include avoidance of ill contacts and possibly preconceptional immunization before influenza season. The potential effect of antipyretics is unclear. In a reanalysis of the BWIS, use of antipyretics was associated with an attenuation of the fever-associated risk for congenital heart defects (192), but more data are needed to confirm this finding. Finally, two studies reported that periconceptional use of multivitamin supplements among women with febrile illness reduced the fever-associated risk for congenital heart defects (18,189), suggesting a further benefit of supplement use.

Maternal Phenylketonuria

Maternal phenylketonuria (PKU) (women with PKU and high blood phenylalanine levels during pregnancy) is a teratogenic condition, with devastating effects on the fetus's brain and sometimes the heart (193–195). Specific heart defects associated with maternal PKU include left-sided defects (coarctation of the aorta to hypoplastic left heart syndrome), tetralogy of Fallot, septal defects, and possibly patent ductus arteriosus (193–195). Estimated relative risk has been high (6 to 15), and in one study, the absolute risk for heart defects was 14% (34 of 235 pregnancies) among pregnancies exposed to high levels of phenylalanine (193). Strict control of phenylalanine levels from before conception reduces considerably the risk for heart defects and other adverse outcomes in the child (193–195).

The prevalence of women of childbearing age with PKU is unknown. However, assuming an average birth prevalence of PKU of 1 in 20,000 births in the United States (higher in whites, lower in blacks), an estimated 100 girls with PKU are born every year in the United States. With universal newborn screening and appropriate early treatment, essentially all will reach childbearing age and eventually be at risk for having an affected pregnancy. Children of women with uncontrolled PKU continue to be born with a variety of physical and neurodevelopmental disabilities, demonstrating that implementing prevention remains difficult and complex. Many factors influence the desired adherence to the strict metabolic diet needed to control phenylalanine levels, including poor access to medical care, lack of reimbursement for medical foods, practical difficulties with implementing the diet, psychosocial issues, and the need for careful pregnancy planning. A comprehensive treatment approach is required. It should start before conception, and continue through the birth of the child. Proposed elements of the approach include education of girls with PKU from adolescence, preventing unplanned pregnancies, psychosocial support, and improved access to treatment (196). Novel medications such as sapropterin, which can reduce phenylalanine levels in responsive women with PKU, could also help improve metabolic control during pregnancy (196).

Thalidomide and Retinoic Acid Congeners

These medications, quite different in molecular structure and mechanism of action, are grouped here because they are established, potent teratogens associated with some of the highest

teratogenic risk in the literature, including for congenital heart defects (3). In addition to magnitude of risk, these medications are also concerning because of the severity of the heart defects they typically cause, including complex conotruncal anomalies, and the frequent presence of extracardiac defects (197–199). From a prevention perspective, retinoic acid and its congeners, which include isotretinoin and etretinate, are also concerning because they may be used by young women for the treatment of acne and other skin conditions (200). Strict regulatory guidelines have been issued in some but not all countries, and exposures continue to occur (141,200,201).

Epilepsy and Antiepileptic Drugs

Most women with epilepsy have uneventful pregnancies and give birth to healthy newborns. However, considerable data, recently reviewed (202), indicates that some antiepileptic drugs (AEDs) can increase the risk for birth defects. This is particularly clear in experimental animals, in whom congenital heart defects are reported to be among the most common birth defects associated with AEDs, followed by orofacial clefts, hypospadias, skeletal defects, and for valproate in particular, neural tube defects (202).

In human pregnancies, the AEDs, rather than epilepsy itself, seem to be the main, though perhaps not the only determinant of teratogenic risk (202–204). The precise parameters of risk are not clear. Pooling data from different studies is challenging and sometime suspect, because of the heterogeneity in methods and study quality. A more recent approach is the use of networks of pregnancy registries sharing common methods and data (204,205). In a pooled review (206), the absolute risk for congenital malformations as a group among women using AEDs was 7%, about three times higher than the pooled reference group (and the group of women with epilepsy not using AEDs). The risk varied by type of AEDs and appeared to be higher for valproate (206). Risk was also higher with polytherapy and with higher AED doses, possibly with a threshold effect (202,206–210). Medications associated with teratogenic risk include phenytoin, hydantoin, and valproic acid, and among newer agents, carbamazepine and lamotrigine (211–216).

The specific risk for congenital heart defects is not well characterized. For carbamazepine, one study in India suggested an increased risk for congenital heart defects (217), but this was not confirmed in a large cohort study in the United Kingdom (218). For phenobarbital, several studies reported the occurrence of congenital heart defects in exposed pregnancies (203,212,217,219), but the small number of cases and the variability among studies make it difficult to establish conclusively the presence and magnitude of cardiac risk (202).

In the United States, seizure medications are prescribed for an estimated 1 million women (19 per 1,000 population) (141) potentially affecting an estimated 30,000 to 75,000 pregnancies every year (141,204). Prevention requires a joint effort by women and physicians. From a management perspective, withholding AEDs is usually not a realistic option for most women, because many women with epilepsy will need AED treatment during pregnancy to prevent or control seizures (202,204). Preconceptional counseling is crucial, as is the strategy of trying to avoid starting young girls on AEDs with known teratogenic effects or switching to other AEDs before conception (141,214–216,220).

The mechanism of teratogenic action is still unclear. Some AEDs (carbamazepine, phenobarbital, phenytoin and primidone) are known to alter folate metabolism in early pregnancy at least in some women. This finding has led to investigate whether supplementation with folic acid might mitigate the teratogenic risk associated with some AEDs, particularly valproic acid. The overall evidence so far, reviewed by Hill and

collaborators (202) does not suggest that there is a specific protective effect among women on AEDs (202,207,218,221). Nevertheless, folic acid supplementation is still recommended in women on AEDs because AEDs may increase the risk for malformations in women with low blood folate levels (202) and because of the overall benefits of supplementation outside of the specific risk associated with AEDs.

Lithium

Lithium is used for manic-depressive disorders, and has been in clinical practice for decades in many countries. Approval by the United States Food and Drug Administration dates from 1970. Because lithium was found early on to be teratogenic in experimental animals, several studies were initiated to assess the risk for congenital malformations in humans. Data through 1994 have been reviewed in detail (222). An early report from the Danish Lithium Babies Registry, a voluntary reporting system (223), described 188 babies born of exposed pregnancies, of which six (5%) had a congenital heart defect, including two cases (1.7%) of Ebstein anomaly (223). The final report, 3 years later (224), described 225 exposed pregnancies, of which 25 had birth defects (11%), including 18 with congenital heart defects (8%) and six with Ebstein anomaly (2.7%). Using these data together with a base birth prevalence for Ebstein anomaly of 0.6 per 10,000 (Table 25.3), a crude relative risk of about 400 can be calculated. However, such estimates, as noted also in first reports, are unrealistic because of the reporting biases that can affect voluntary registries. In fact, later studies suggested that whereas an excess risk for congenital heart defects probably exists, it is much lower than initially thought (222,225,226). More specifically, a cohort study from Sweden, using a series of data linkages, identified 59 pregnancies exposed to lithium alone and of these seven had birth defects, and four (6.8% overall) had congenital heart defects, for an estimated relative risk of 7.7 (95% confidence interval, 1.5 to 41.2). Notably, none had Ebstein anomaly. Another cohort study, from the United States, evaluated 148 pregnancies of women with first trimester use of lithium, identified through a teratogen information system (225). The women had contacted the service because of concerns about the medication. A matched set of women who contacted the same service but had not been exposed to known teratogens was selected as the reference cohort. Overall birth defect rates in the two groups were similar (four cases in the exposed cohort, three in the reference group). The formal relative risk estimate for congenital heart defects was 1.2 (95% confidence interval, 0.1 to 18.3). However, one of three affected pregnancies in the exposed cohort had Ebstein anomaly. In addition to these two cohort studies, several case-control studies with data on birth defects, some specifically on Ebstein anomaly, are available and have been reviewed in detail (222). Briefly, these studies reported very few exposed pregnancies and the associated odds ratios did not indicate an increased risk for congenital heart defects.

Based on the cohort studies, it appears that the risk associated with first trimester use of lithium is probably increased moderately for birth defects overall, perhaps two- to threefold. The specific risk for congenital heart defects seems to be in the same range or somewhat higher, increased from two- to sevenfold. The risk for Ebstein anomaly in particular is very likely increased but the magnitude is unclear.

These findings can help clinicians assess the use of lithium during pregnancy in an appropriate context of risks and benefits (37,222,226). Women with manic-depressive conditions may benefit from targeted preconceptional counseling and prenatal care, also because they could be at risk for adverse pregnancy outcomes independent of lithium exposure (222,225–227). Some reports suggest that in experimental animals, lithium-induced embryopathy can be prevented by folate supplementation if

administered in doses higher than those provided by a typical multivitamin supplement (228,229). Whether or not this can be extrapolated to women is unknown, but suggests nevertheless that women who need to use lithium in pregnancy should adhere to basic preconceptional care recommendations, including taking folic acid from before conception. Whether or not they could benefit from higher doses of folic acid than the 0.4 mg currently recommended for all women is unknown.

Antidepressants

Antidepressants are a heterogeneous group of medications used for mood disorders. Several have been evaluated for the risk of birth defects. For congenital heart defects, results are often inconsistent and vary across different types and classes of antidepressants. Accumulating data seem to indicate a possible mild to moderate risk for congenital heart defects associated with paroxetine, a selective serotonin reuptake inhibitor (SSRI). Two formal meta-analyses have been published (230, 231). The more recent study (230) generated a summary relative risk estimate for heart defects of 1.24 (95% CI, 1.08–1.43), slightly higher for the group of “combined heart defects.” It is still debated whether such modestly increased risk is entirely driven by medication use or also in part by the underlying risk factors in the select group of women who take the medication (230,232). Studies on paroxetine are also inconsistent regarding the specificity of the association; for example, one study reported an increased risk for right-sided obstructive heart defects (233), another for atrial septal defects but no other heart defect (234), and another still for minor defects such as ventricular septal defects and bicuspid aortic valve (235).

Another antidepressant recently studied for possible cardiac teratogenicity is bupropion, an atypical antidepressant (different from SSRIs) used also for smoking cessation. Studies so far include the pharmaceutical company’s registry data, which showed a potential association, one cohort study (236), reported as negative, and a case-control study (237), which showed a positive association with left-sided obstructive heart defects (odds ratio 2.6, 95% confidence interval 1.2 to 5.7).

Although the magnitude of putative risks seems small, the high prevalence of use of these medications in women of child-bearing age makes them potentially important. In counseling women, the appropriate balance of risk and benefits needs to be reached, taking into account not only the potential risks for some heart defects, but also the serious consequences of untreated or undertreated depression during pregnancy.

ACE Inhibitors

Angiotensin converting enzyme (ACE) inhibitors are medications widely prescribed to control hypertension. They are contraindicated in the second and third trimester of pregnancy because of effects on fetal blood pressure and renal function, leading to fetal toxicity and death (238,239). For this reason, the United States Federal Drug Administration has required warning on ACE inhibitors (currently, category D) since 1992. Questions of cardiac teratogenicity following first trimester were raised by a study in 2006 that reported an increased risk for heart defects in babies of women who had been prescribed ACE inhibitors during pregnancy (240). The study linked coded outcomes with prescription data within the Tennessee Medicaid database and the reported association was based on seven occurrences of atrial or ventricular septal defects and two of patent ductus arteriosus (240). No association was found with the use of other antihypertensive medications, suggesting a specific effect of ACE inhibitors (240). However, such specific association was not found in several subsequent studies, including the population-based National Birth Defect Prevention Study (241), the Swedish Birth Registry (242), a collaboration of Teratogen Information Services in Israel and

Italy (243) and the Kaiser Permanente system in California (244). Some of these studies were also summarized as part of a meta-analysis (245). The pattern that emerges from these studies is that ACE inhibitors are either not a risk factor for congenital heart defects or the associated risk is similar to that present in mothers with untreated hypertension or treated with many other classes of antihypertensive medications. Such a pattern does not support a specific effect with ACE inhibitors. The mild-to-moderate risk associated with antihypertensives could have different causes, including the underlying maternal hypertension. For example, in one study, the exposure to ACE inhibitors was associated with an increased risk for congenital heart defects when compared to normal controls, but not compared to untreated hypertensive controls (244). Bias and confounding could also play a role. Hypertension commonly occurs in women with obesity and diabetes, which are risk factors for congenital heart defects, and these factors have not been consistently accounted for in all studies. In summary, current data does not support the notion that first trimester exposure to ACE inhibitors confers an increased, specific risk for heart defects, above that possibly associated with maternal hypertension (treated or untreated) or with the common comorbidities of hypertension, such as obesity and diabetes. Nevertheless, ACE inhibitors are contraindicated in pregnancy, mainly for their established deleterious effects in the second and first trimester. Women with hypertension should be appropriately counseled, ideally before conception, so they can start pregnancy on a safer medication that appropriately controls hypertension.

Other Medications

Trimethoprim-sulfonamide and sulfasalazine have been associated with a mild-to-moderate increase in risk for congenital heart defects (246,247). In one study, the use of folic acid supplements decreased the excess risk associated with these compounds (247).

Obesity

To date, the evidence for obesity is mixed. Some positive associations have been reported, but it is unclear to what extent they reflect causality or are due to confounding. Both positive and negative findings have been reported for heart defects in aggregate, as well as for specific phenotypes such as septal defects, left- or right-sided obstructive defects, and some conotruncal defects (16,248–255). Among positive studies, the overall magnitude of risk is small, with most odds ratios under 1.5, with both higher and lower risk estimates for specific cardiac phenotypes. Some studies appear to indicate a positive trend of risk with increasing body mass index (255), whereas other did not.

Epidemiologically, it can be very challenging to examine the contribution and interaction of these factors among pregnant women with obesity. For example, obesity may contribute to and be present together with gestational diabetes (256) and perhaps unrecognized type 2 pregestational diabetes. This co-occurrence or confounding could vary by study, depending on the completeness of diabetes screening among study participants. Using appropriate biomarkers could be very helpful, but few are well characterized so far.

Nevertheless, from a prevention perspective, obesity is a significant concern even if the excess teratogenic risks were small, because of its high and rising frequency in many developed and developing countries (174). According to estimates from the United States CDC (257), the overall prevalence of obesity among women aged 20 to 39 years in the United States between 1976 to 1980 and 2007 to 2008 increased from 15% to 34%. These rates varied depending on race-ethnicity, and were higher among non-Hispanic blacks and lower among

non-Hispanic whites (257). Obesity rates also appear to be inversely correlated to education level, with the highest rate among women with less than high school education (258). With such high frequency and complex patterns of exposure, small risks can translate into many affected pregnancies, particularly in groups of the population that are socioeconomically disadvantaged. Interventions will need to take these factors into account, as well as related health issues such as diabetes. Finally, limited evidence suggests a possible mitigating effect of multivitamin supplementation on obesity-related risk for heart defects (251). If confirmed by further research, vitamin supplementation could represent an adjunct approach to reducing the birth defect burden potentially associated with the obesity epidemic.

Caffeine

Caffeine is frequently consumed and has proven cardiovascular effects in mother and fetus. However, the recent literature has been extensively reviewed (259) and did not find strong evidence suggesting an excess risk for congenital heart defects in several larger studies from Finland (260,261), Denmark (262), and the United States (16,263–265).

Alcohol

Alcohol is an established human teratogen, and is known to cause a wide range of structural malformations and neurodevelopmental abnormalities (266,267). The association with heart defects has been less impressive, with inconsistent or negative results in several large studies (16, 260, 261, 268–270), but with some positive associations as well (271–274).

Methodologic issues, including the challenge of documenting exposure reliably and precisely, make studies of alcohol effects in humans especially difficult. In case series with established fetal alcohol syndrome, congenital heart defects and in particular septal defects are common (274). In the context of case-control studies of structural malformations, these findings have been difficult to replicate. In the BWIS, significant associations with alcohol exposure were limited to small ventricular septal defects and only in women who reported heavy consumption (16). In a series of studies from Finland, possible associations were found with ventricular septal defects, atrial septal defects, and possibly conotruncal defects, although dose-response patterns were unimpressive (260,268,269). In the Atlanta population-based case-control study, associations with conotruncal anomalies were evaluated and none were found (270). In two case-control studies from California, alcohol use was reportedly associated with a modestly increased risk for conotruncal heart defects, particularly D-transposition of the great arteries, though the authors noted that the estimates were imprecise and compatible with chance or modest bias (275,276). In the Danish National Birth Cohort study, low-to-moderate levels of alcohol on a weekly basis or occasional binge drinking during the early part of pregnancy was not significantly associated with ventricular or atrial septal defects, with point estimates between 1.1 and 1.4 depending on reported amounts of alcohol use (271). Scarce data are available on possible interactions. In a case-control study in Arkansas, modestly elevated risks for heart defects (odds ratio of 1.7) were found with alcohol use only in women with certain polymorphisms of genes for the folate pathway (273). A case-control study from California that evaluated whether vitamin supplements used in women modified the alcohol-associated risk for congenital heart defects gave inconclusive results, and no specific pattern of risk was found (189).

In summary, although babies with full-blown fetal alcohol syndrome commonly have defects, it is still unclear whether mild-to-moderate alcohol use is associated with an increased

risk for heart defects. However, the global teratogenic effects of alcohol use, particularly on the fetal brain, make prevention of this exposure an important public health priority (141,277). According to one study, approximately seven million women of childbearing age in the United States are frequent drinkers, and without preconception interventions, alcohol misuse might affect approximately 577,000 births per year (141).

Smoking

Although smoking is an established risk factor for low birth weight, preterm birth, and other adverse outcomes, evidence for cardiac teratogenicity is unclear. Some studies suggest a small excess risk (odds ratios, 1.1 to 1.6) for atrial septal defects and pulmonic stenosis (278–281), and perhaps for some conotruncal defects (odds ratio below 2) (16,189,279). Higher risk estimates have been reported with heavier smoking in some, but not in all studies.

As with other common exposures, even a small increased risk for heart defects is of concern because of the high number of women who smoke. In 2003, an estimated 11% of pregnant women in the United States smoked during pregnancy (141). In many countries, rates of smoking in women are high and increasing (282).

In summary, the relative risk for congenital heart defects is probably low and causality is perhaps not entirely established. Nevertheless, smoking is in general bad for the health of women (cancer, heart disease) and their pregnancies (low birth weight, sudden infant death). These reasons strongly support the inclusion of smoking cessation as a priority target for prevention interventions.

Vitamins: Epidemiologic Evidence for Risk and Protection

The interest on the relation between nutrition and congenital heart defects continues to increase. In part, this may be the result of the public health success story of folic acid in preventing neural tube defects. Supplementation campaigns and mandatory food fortification programs have been implemented in several countries, including the United States, Canada, several countries in Latin America, and Australia. Fortification in particular has led to a major population-wide reduction in the prevalence of spina bifida and other neural tube defects (283). From this successful chapter of translating epidemiology into prevention, research has moved in two directions: assessing whether folic acid may prevent other birth defects, including heart defects, and expanding the scope from folic acid to the larger network involving one-carbon metabolism and substrate methylation of which folic acid is part (284). These pathways include several other vitamins, including pyridoxine-B6 and cobalamin-B12, as well as several enzymes and transporters, encoded by genes that often have common functional polymorphisms. Of interest is also the increasing evidence that alterations in folate metabolism and folate levels could be associated with other common maternal risk factors such as smoking. These novel data open the possibility of interactions between multiple genetic and environmental factors. In addition to single nutrient analyses, nutritional epidemiologists increasingly tend also to assess dietary patterns, since people eat foods rather than nutrients. In fact, many nutritional strategies in adult cardiology and medicine to prevent cardiovascular disease and stroke are based on modifying dietary patterns (e.g., with the Mediterranean or the Dietary Approaches to Stop Hypertension-DASH diets), rather than on exclusively controlling a single or a few micronutrients.

Similar approaches to congenital heart defects could prove fruitful (285) but are currently still in their infancy.

For now, most of the published data relate to micronutrients and vitamins. This section will focus on two vitamins in particular, vitamin A and folic acid, with additional discussion on multivitamin supplements.

Vitamin A: Not Too Little, Not Too Much

Vitamin A is an essential vitamin, widely available in over-the-counter supplements. High-dose formulations are easily found. Vitamin A is an important molecule in the synthetic pathway of retinoic acid, a potent transcription factor and established cardiac teratogen, and for this reason it has been assessed in several epidemiologic studies of birth defects.

Vitamin A is typically marketed in one of two forms, beta-carotene and retinol. In all studies that have looked at it, beta-carotene (a provitamin A) has not been associated with increased risks for congenital heart defects (286,287). Retinol, on the other hand, is preformed vitamin A, and has been associated in some studies with an increased risk for congenital heart defects. Specifically, two studies described a moderate to strong association (odds ratios >5) between use of >10,000 IU of retinol and the occurrence of conotruncal heart defects, in particular D-transposition of the great arteries (286,287). Another study, which evaluated the use but not the dose of vitamin A, reported a weaker association (288). In four other reports, however, the association was not confirmed (289–292). Nevertheless, it appears reasonable to recommend avoiding high-dose retinol supplements in the periconceptional period and, if vitamin A is indicated, favor supplements containing beta-carotene.

Folic Acid and Multivitamins: An Evolving Story

Because of its established protective effect on neural tube defects, the use of folic acid for all women of childbearing age or those who do not actively exclude a pregnancy is recommended by medical organizations, public health agencies, and lay organizations in many countries. Thus, assessing whether or not folic acid should be recommended to prevent congenital heart defects could seem a useless exercise. However, this view is simplistic. Identifying a protective effect on heart defects, if indeed one exists, would be beneficial in several ways. It would add to the potential benefits of folic acids, and the associated “return on investment” that could be achieved with more expansive supplementation and fortification programs worldwide. Identifying a protective effect may require approaches and methods that are different from those used to examine neural tube defects. For example, one might need to evaluate higher doses of folic acid or multivitamins rather than folic acid alone, as there is no guarantee that all folic acid-responsive birth defects are as sensitive to folic acid as are neural tube defects. This has implications for research and practice. If preventing congenital heart defects requires high doses of folic acid or multivitamins, then the current fortification programs, which typically use small amounts of folic acid alone, may achieve no or partial results. Also, identifying a role for folic acid or molecules in the broader context of folic acid-related biochemical networks could help understand aspects of the etiology of congenital heart defects, including gene-environment interactions, and ideally open further avenues for prevention. Finally, researching the effect of folic acid in humans has become more complex. Clinical trials comparing folic acid with placebo, now that folic acid is known to protect against serious nervous system defects, would be unethical. Other options would be available, such as evaluating high dose versus standard dose of folic acid/multivitamins, or including in a vitamin trial also a cohort of women who refused taking folic acid, but all these options are imperfect and challenging.

EVIDENCE FROM CLINICAL AND EPIDEMIOLOGIC STUDIES

The main epidemiologic and clinical studies, conducted in the absence of fortification, are described in Table 25.8 together with their main design features and findings.

These studies include one randomized clinical trial from Hungary (293), and four case-control studies from the United States (19,294,295) and the Netherlands (296). All studies were conducted in the absence of universal food fortification.

The randomized clinical trial (293) enrolled women from before conception. Participants were randomized to receive a multivitamin with folic acid or a placebo-like pill containing trace elements. These two cohorts were followed from conception through after the child's birth and their pregnancy outcomes were evaluated. The primary endpoint of the study was the occurrence of neural tube defects. Secondary endpoints included fetal deaths and other structural malformations, including heart defects. The case-control studies evaluated retrospectively the frequency of use of multivitamin supplements, known or presumed to contain folic acid, in case-mothers and control-mothers. Two of the studies evaluated a broad range of heart defects (19,296), whereas the remaining three (294,295,297) were restricted to conotruncal defects (and in one study, also ventricular septal defects).

The findings are illustrated graphically in Figure 25.16.

In the randomized clinical trial (293), fewer women taking the multivitamin with folic acid had a child with a congenital heart defect compared to the reference cohort, for a statistically significant risk reduction of 58%. This finding was driven mainly by the lower rate of conotruncal and septal defects (293,298). However, the available sample size limited the precision of the risk estimates for the subtypes of heart defect.

The case-control studies confirm some of these findings, but not consistently. For example, the two case-control data that assessed heart defects in the aggregate also found an overall reduced risk (19,296), though the magnitude of the apparent protective effect was lower than in the randomized clinical trial (25% vs. >50%). For conotruncal and septal defects, the evidence is mixed. Two case control studies did not show evidence of risk reduction for conotruncal defects (295,297), whereas three others did (19,294,296). For (ventricular) septal defects, one case-control study did not show evidence of risk reduction, (297) whereas two others did (19,296). Why the studies are not entirely consistent is unclear, but methodologic differences as well as varying degrees of bias and confounding could have played a role.

In summary, at this time the preponderance of clinical and epidemiologic data, including findings from a randomized clinical trial, seems to indicate a moderate risk reduction for congenital heart defects in the aggregate with periconceptional use of a multivitamin supplement containing folic acid. However, not all studies are consistent, and more data are needed. Ideally a new, well-designed clinical trial or a large, carefully implemented prospective case-control study, preferably with biologic markers, could provide conclusive data on this important issue.

RATES AFTER FORTIFICATION

Several countries in North and South America and Middle East, as well as Australia (but no countries in Europe yet), have introduced folic acid fortification, that is, have added variable amounts of folic acid to the food supply, typically in cereal grain products that make their way into common staples such as breads and pasta. The main goal was to reduce the occurrence of neural tube defects by increasing folic acid consumption in the population as a whole. Fortification has also allowed the opportunity to examine changes in the rates of major congenital heart defects in response to overall changes in folic acid consumption. Figure 25.17 summarizes the few available population-based studies, all from North America.

TABLE 25.8

Prevention by Vitamin Use: Summary of Studies on Periconceptional Use of Vitamins and Occurrence of Congenital Heart Defects

Type of Study	Year (Reference)	Population-Based	Study Participants	Exposure	Relative Risk (95% Confidence Interval)		Ventricular Septal Defect
					Heart Defects (overall)	Outflow Tract Defects	
Clinical Trials							
Randomized clinical trial	1998 Czeizel et al (293)	—	2,471 women on MV supplements; 2,391 on trace elements	MV pill with 0.8 mg folic acid	0.42 (0.19–0.98)	0.48 (0.04–5.34)	0.24 (0.05–1.14)
Observational Studies							
Case-control	1995 Shaw et al. (294)	Yes	207 with OTD, 481 controls	MV pill	—	0.53 (0.34–0.85)	—
Case-control	1997 Scanlon et al. (295)	Yes	126 with OTD, 679 controls	MV pill with folic acid	—	0.97 (0.6–1.6)	—
Case-control	1999 Werler et al. (297)	No	157 with OTD, 186 with VSD, 521 controls	MV pill	—	1.00 (0.70–1.50)	1.20 (0.80–1.80)
Case-control	2000 Botto et al. (19)	Yes	958 with heart defects, 3,029 controls	MV pill	0.76 (0.60–0.97)	0.46 (0.24–0.86)	0.61 (0.38–0.99)
Case-control	2010 Beynum et al. (296)	Yes	611 with heart defects, 3,343 controls	≥0.4 mg folic acid alone or as MV pill	0.74 (0.62–0.88)	0.69 (0.47–1.03)	0.56 (0.43–0.74) VSD or ASD

MV, multivitamin; OTD, outflow tract defects; VSD, ventricular septal defects; ASD, atrial septal defect.

In the United States, a study using birth defect surveillance data from 23 state programs compared rates of selected congenital heart defects in 1999 to 2000 versus 1994 to 1996 (299). For heart defects, the study reported a modest (12%) but significant decline in D-transposition of the great arteries (12% reduction, rate ratio 0.88 with 95% CI 0.81 to 0.96), but not for tetralogy of Fallot or ventricular septal defects (299). In Canada, studies from two provinces also reported a modest decline in some heart defects after fortification. In Alberta, researchers using data from a well-established population-based birth defect registry reported a 20% decline in secundum atrial septal defects (rate ratio 0.80, 95% CI 0.69 to 0.93), but not for other heart defects (300). In Quebec, researchers using linked administrative databases evaluated trends of a group of severe heart defects, including conotruncal defects (60% of the case group), single ventricle, and endocardial cushion defects (301). They reported a significant decline of these defects, 6% for every year after fortification (yearly rate ratio 0.94, 95% CI 0.90 to 0.97).

Limited additional information is available from Latin America, where several countries, including Chile, Argentina, and Brazil, introduced fortification at different times and levels. Unlike in North America, no population-based studies are available yet. However, researchers from the Latin American Collaborative Study of Congenital Malformations

(ECLAMC) evaluated rates of selected birth defects from a small sample of hospitals in Chile, Argentina, and Brazil before and after fortification (302). For heart defects, they reported a statistically significant reduction of septal defects. This decline was seen in Argentina and Brazil but not in Chile. In a similar pattern, a moderate nonsignificant decline in an aggregate group of severe heart defects (conotruncal defects, single ventricle, endocardial cushion defects) was observed in Argentina (rate ratio, 0.66) and Brazil (rate ratio, 0.77), but not in Chile (rate ratio, 1.28). By contrast, the decline for neural tube defects was marked and consistent across the three countries (302).

In summary, the few postfortification studies available to date do not suggest a marked or consistent decline in congenital heart defects. Some statistically significant reductions have been observed, but so far these have not been consistent across phenotypes and geographic areas, even within the same country. Interpreting these inconsistencies is challenging. Contributing factors could include variations in the effectiveness of fortification (as documented by blood folate levels) and in study methodology (inclusion criteria and classification scheme). In addition, without a concurrent control group, it is difficult to assess the influence of structural changes in reporting and ascertainment, including the influence of elective terminations of pregnancy. Finally, as the ECLAMC researchers note in their report from Latin America (302), studies based

Figure 25.16. Estimated relative risks for congenital heart defects associated with periconceptional use of vitamin supplements with folic acid. Lines represent 95% confidence intervals. Multivitamin supplementation and risk of birth defects. *Am J Epidemiol* 1999;150:675–82.)

on small convenient samples of hospitals can provide detailed data but also be affected by biases, including referral bias.

In general, the data from postfortification studies (Fig. 25.17) are less compelling than those from the clinical trial and observational studies (Fig. 25.16). However, this seems to be true even for neural tube defects, for which the protective effect of folic acid is well established: with fortification, the reduction in occurrence is less and take longer compared to what is seen in observational studies and clinical trials. But the different findings for heart defects and neural tube defects can have other explanations. For example, folic acid may not be effective for heart defects at all; it may be effective only in larger amounts than those typically consumed through fortification or standard folic acid pills (0.4 mg); or it may be effective mainly as part of a multivitamin supplement. In fact,

the reported studies all looked at multivitamin supplement use rather than folic acid alone.

ANCILLARY DATA FROM GENETIC AND ENVIRONMENTAL STUDIES

Potentially relevant data have been generated by studies looking at interactions between multivitamin supplement use and risk factors such as certain medications (247), febrile illnesses (18,189), and pregestational diabetes (161). Findings from one of these studies is illustrated in Figure 25.18 (18).

The odds ratio estimated the relative risk for the different types of heart defects among women reporting a first trimester febrile illness. The figure shows these odds ratios in women who took a multivitamin supplement in the periconceptional period (fever, with MV) and in women who did not take the multivitamin supplement (fever, no MV). Although these risk

Figure 25.17. Prevalence rate ratios showing changes in reported birth prevalence of selected congenital heart defects in North America after flour fortification with folic acid. Lines represent 95% confidence intervals. Prevalence rate ratios above 1 suggest increased rates after fortification, prevalence rate ratios below 1 suggest decreased rates. (Data from Canfield MA, Collins JS, Botto LD, et al. Changes in the birth prevalence of selected birth defects after grain fortification with folic acid in the United States: findings from a multi-state population-based study. *Birth Defects Res A Clin Mol Teratol* 2005;73:679–689 (US selected states); Godwin KA, Sibbald B, Bedard T, et al. Changes in frequencies of select congenital anomalies since the onset of folic acid fortification in a Canadian birth defect registry. *Can J Public Health* 2008;99:271–275 (Canada Alberta); Ionescu-Ittu R, Marelli AJ, Mackie AS, et al. Prevalence of severe congenital heart disease after folic acid fortification of grain products: time trend analysis in Quebec, Canada. *BMJ* 2009;338:b1673 (Canada Quebec).)

estimates have wide confidence intervals, there appears to be a fairly consistent trend for lower risks among multivitamin users. This would suggest that taking the supplement could mitigate the risk for congenital heart defects associated with fever (18).

Regarding genetic susceptibility in humans, several studies have looked at risk for congenital heart defects in the presence of polymorphisms in several metabolic pathways, but mainly the folate/one-carbon metabolism pathway (303–306). So far, both positive and negative findings have been reported. For folate-related genes, most studies do not show an association with conotruncal or other heart defects (307–312), although some positive associations have been reported (37,313–315). Two studies also suggest a possible gene-nutrient interaction between folate supplementation and presence of a

polymorphism in the reduced folate carrier gene (RFC1). Specifically, these studies found a lower risk for some heart defects associated with the RFC1 polymorphism among mothers who used vitamin supplements in the periconceptional period (316,317).

In summary, folic acid and multivitamin supplementation could have a role in reducing the risk for some congenital heart defects, but evidence, while suggestive, is not conclusive. If confirmed, the impact would be considerable, because the fraction of preventable heart defects may be large. Also, vitamins, including folic acid, are inexpensive and easily transportable, making prevention through vitamin supplementation a viable strategy also in developing countries. Because of the potential implications, a large randomized trial of vitamin supplementation (vs. the recommended dose of folic acid alone) would be very helpful. The resources needed for such study would be considerable, but will likely be minimal compared to the high societal and personal costs of heart defects.

From a practical perspective, however, clinicians need not wait for such a trial. Because of the established protective effect against neural tube defects, daily periconceptional use of folic acid is recommended for all women of childbearing age. By simply promoting periconceptional use of a multivitamin supplement containing folic acid (400 µg), pediatric cardiologists would (and should) provide all women with the benefits of a reduced risk for a neural tube defect-affected pregnancy. The protection against heart defects, to the extent that is present, will be an added benefit, at no additional cost or risk.

STRATEGIES AND TOOLS: EPIDEMIOLOGY OF PREVENTION

Prevention is motivated by incentives and driven by evidence. The next step, implementation, requires strategies to maximize the impact of interventions, and tools to make prevention practical, coherent with the goals, and consistent across practitioners. A broad strategic framework for disease prevention and health promotion is illustrated by the Health Impact Pyramid (Fig. 25.19) (318).

This five-tier model emphasizes that to prevent a large fraction of disease, clinical care and counseling are important, but even more important are interventions that address the broader context of health in society. For example, using diabetes as a model, clinical care and counseling are crucial, but require much individual effort over time by both provider and client and typically reach only a fraction of women with diabetes (318). For maximum effectiveness, diabetes prevention needs to be tackled also through broad societal interventions, such as promoting health education and healthy habits (nutrition, physical activity, obesity prevention), helping make healthy choices the default choices (establishing pedestrian friendly areas, increasing taxes on junk food and beverages), and implementing sustained, long lasting interventions (ad campaigns, including those targeted at youth, screening campaigns) (318). The spectrum of interventions may of course vary depending on the target exposure. For example, to prevent rubella embryopathy, long-lasting interventions (Fig. 25.19) such as immunizations in preteens will play a major role. To decrease smoking, one may need to focus on early education campaigns to reduce the number of first-time smokers and on improvement in socioeconomic conditions, as in many countries socioeconomic status and education levels are inversely related to smoking rates.

This broad strategic framework is crucial not only for primary prevention, but also for reducing complications and optimizing health in people with heart defects

Figure 25.18. Interactions with multivitamin supplement use, possibly mitigating the effect of febrile illness on the risk for selected congenital heart defects. Symbols represent odds ratios for fever, in the absence and in the presence of multivitamin supplement use. Lines represent 95% confidence intervals. Odds ratios above 1 suggest increased risk, odds ratios below 1 suggest decreased risk compared to the reference group. (Data from Botto LD, Erickson JD, Mulinare J, Lynberg MC, Liu Y. Maternal fever, multivitamin use, and selected birth defects: evidence of interaction? *Epidemiology* 2002;13:485–488.)

(secondary prevention), and fits with the increasing attention to prevention throughout the lifespan, from preconception to adults (Fig. 25.2). Clinicians can play a major role not only as providers of individualized clinical care, but also as members of professional organizations that can influence policy making.

Every Woman, Every Time

Moving from this prevention framework to implementation, it is important to characterize the main target population for interventions. Focusing on primary prevention, a preferred target historically have been high-risk families—typically women with family history of congenital heart defects or strong risk factors—and interventions were aimed shortly before conception or in early pregnancy. However, for maximum impact, it is increasingly realized that a more appropriate target is all women of childbearing age. There are several reasons for this shift in focus. First, most babies with heart

defects are born to women and families that are not known to have risk factors, such as having had an affected child. Also, women may not report routinely or even be aware of risk factors, even major ones such as diabetes (175). Second, prevention needs to start before conception. However, most pregnancies worldwide are unplanned (in the United States, over half) and many women find out they are pregnant several weeks after conception. Thus, optimizing women's health before conception requires ongoing attention throughout the childbearing years.

In summary, to maximize the opportunities for prevention, every clinician needs to promote prevention with every woman at every clinical contact—an approach that has been summarized as “every woman, every time.” One significant advantage of this approach is the potential not only to prevent some heart defects, but also improve women's health generally, together with reducing a broad range of adverse pregnancy outcomes. Diabetes, infections, smoking, and lack of folic acid use are risk factors for several types of extracardiac malformations, as well as for preterm birth, intrauterine growth restriction, and infant deaths.

Figure 25.19. The Health Impact Pyramid: designing prevention strategies for maximum population impact. (Modified and redrawn from Frieden TR. A framework for public health action: the health impact pyramid. *Am J Public Health* 2010;100(4):590–595.)

Choosing the Battles: Going for the Greatest Impact

Having broadly identified the target population for prevention (every woman, every time), one is still confronted with a wide range of heterogeneous risk factors (Table 25.7). The final goal is to prevent all preventable congenital heart defects by intervening on all risk factors. However, strategically, it is helpful to reassess these risk factors in terms of their potential for prevention. One useful metric in planning strategies is the attributable fraction of disease, the fraction of cases in the population that is attributable to a risk factor. This is a fraction of disease that could be prevented if the factor was controlled or eliminated. As illustrated previously (Fig. 25.15), the attributable fraction for a risk factor depends not only on its relative risk for disease but also on its frequency in the population.

Risk factors with the highest attributable fraction, assuming that effective prevention strategies exist, would be prime candidates for focused efforts. Factors with low attributable

fraction are not necessarily excluded from prevention efforts, particularly if they are easy to identify and treat, and if they are important for other aspects of population health. For example, even if smoking has a low attributable fraction for congenital heart defects, it is a strong risk factor for many other adverse outcomes, and ought to be included in any comprehensive prevention program. Other considerations, in addition to attributable fraction (and therefore relative risk and exposure frequency), include the strength of the evidence for causality, the severity of the associated heart defects, and, because the final goal is the overall health of woman and child, also the effects on other health outcomes. Table 25.9 summarizes these elements for several of the risk factors that have been reviewed.

As the table illustrates, some risk factors, such as pregestational diabetes, have high potential for prevention, combining strong causal evidence, high relative risks for many congenital heart defects (include severe types), increasing frequency in

the population with increasing attributable fraction, and additional impact on women's health and pediatric outcomes. Others are rare (maternal PKU) but can be easily identified and referred for treatment. For a few, such as folic acid supplementation, the evidence of protective effect for congenital heart defects is not conclusive, but the preventive effect on other adverse outcomes (e.g., spina bifida) is so well established and powerful, that it stands to reason to incorporate these interventions in comprehensive strategies of preconceptional health and prevention. Some of these elements are obviously subject to change, as the prevalence of risk factors increase or decrease, and as the knowledge about causality and specificity improve with new studies.

With these caveats in mind, some guidelines for primary prevention can be suggested (3). With some minor modifications and updates, they are summarized in Table 25.10.

Specifically, all women of childbearing age should be encouraged to take a daily vitamin supplement containing

TABLE 25.9

Selected Risk Factors for Heart Defects by their Potential Global Impact on Primary Prevention and Health Promotion

Factor	Strength of Evidence	Estimated Relative Risk (RR)	Frequency of Exposure (FEP) in Women	Potential Attributable Fraction (%)	Prevention Benefits beyond the Heart
Diabetes (pregestational)	Definite	+++	Common, increasing	7%–15% of more For RR = 4 and FEP = 2.5%–6%	Definite: other birth defects, prematurity and other adverse pregnancy outcomes, maternal health
	Many types	4–10	2%–6%		
Select medications	Definite	++	Varies, but can be common	3% For RR = 4 and FEP = 1%–3%	Definite: neural tube defects and oral clefts (valproic acid), retinoic acid and multiple birth defects
	Many types	2–5 or more			
Phenylketonuria, uncontrolled	Definite	+++	Rare	0.5%	Definite: Mental retardation, microcephaly
	LVOTO	~6	<0.01%		
Non use of folic acid, multivitamin	Possible	+	Very common	33% For RR = 2 and FEP = 50%	Definite: prevent 50%–70% of neural tube defects, possibly other birth defects as well
	Septal, conotruncal	~2	50% to >90%		
Fever/Flu	Possible	+	6 to 10%	4% For RR = 2 and FEP = 6%	Probable/definite: neural tube defects, other adverse outcomes
	Septal, RVOTO	~2			
Smoking	Possible	+	Varies, common	10% For RR = 2 and FEP = 11%	Definite: clefts, low birth weight, intrauterine growth restriction, infant death; maternal health
	Septal	~2	10%–15% or more		
Obesity	Possible	+	Common, increasing	4%–6% For RR = 1.2 and FEP = 20%–30%	Possible: neural tube defects Definite: maternal health, diabetes
	Many types	~1.5	20%–30%		

TABLE 25.10

Improving Health, Decreasing Risk: Seven Steps for Primary Prevention and Health Promotion for Baby and Mother

Action	Comment
1. Take a multivitamin with folic acid daily	Folic acid, 400 µg (0.4 mg) or more Avoid high retinol (>10,000 IU)
2. Promote healthy life and habits	Healthy weight, physical activity, nutrition Preconceptional and early prenatal care
3. Screen/target chronic illnesses	Diabetes (may be unrecognized), epilepsy, PKU
4. Screen/stop smoking, alcohol use	Also second hand smoking
5. Screen/assess medication use	Seizure medications, retinoic acid. Check with physician or teratogen information service (OTIS/ENTIS)
6. Avoid close contact with ill individuals, especially with febrile illnesses	Up-to-date immunizations, including rubella; treat high fever early
7. Avoid exposures to heavy metals, herbicides, pesticides, and organic solvents	At work and at home, self or spouse

folic acid, to reduce the occurrence of neural tube defects and possibly also for some congenital heart defects. They should reevaluate and treat chronic conditions from before conception, especially diabetes. Women diagnosed with PKU as infants should be targeted for interventions aimed at ensuring adherence to a low phenylalanine diet before conception and continue it throughout their pregnancy.

Before conception, women who take potentially teratogenic medications (e.g., valproic acid or lithium) and who are not actively excluding a pregnancy should be counseled about risks and benefits and evaluated for a change in type or dose of medication. Unintended pregnancies need to be avoided particularly among women who use strong teratogens such as retinoic acid medications (e.g., Accutane®). Rubella vaccination provides protective seropositivity and prevents congenital rubella syndrome. Because only 20% of women successfully control tobacco dependence during pregnancy, cessation of smoking is recommended before pregnancy (141), not so much to decrease the potential risk for some congenital heart defects, but to decrease the established risks for preterm birth, low birth weight, and other adverse perinatal outcomes. Alcohol misuse is a significant concern. Although the evidence for specific cardiac teratogenicity is mixed, fetal alcohol syndrome and alcohol-related birth defects can be prevented if women cease intake of alcohol before conception.

With respect to obesity, the risk associated with congenital heart defects is not yet convincingly established. However, obesity is associated with several adverse perinatal outcomes, including neural tube defects, preterm delivery, diabetes,

hypertension, and thromboembolic disease. Appropriate weight loss and improving nutritional health before pregnancy reduces these risks. Additional recommendation for preconception care include vaccination for hepatitis B, identification and treatment of HIV/AIDS and sexually transmitted diseases, treatment of hypothyroidism, and reassessment of oral anticoagulant therapy for warfarin users.

These general guidelines can reasonably apply to all women of childbearing age, to prevent the occurrence of congenital heart defects and other congenital anomalies. Pediatric cardiologists, perhaps more than other specialists, will also see and be called to counsel women who have a congenital heart defect or a previously affected child, and who are contemplating (or not actively excluding) another pregnancy. In this group, the search for modifiable risk factors should be especially rigorous. Also, evaluation for underlying genetic conditions (e.g., deletion 22q11), including referral to an experienced medical geneticists, may be extremely helpful in defining and managing recurrence risk. In the setting of prevention of recurrence of neural tube defects, data from a randomized trial has shown the efficacy of high dose (4 mg) of folic acid, with no adverse effect. No comparable data are available for heart defects.

Ideally, these guidelines would be promoted as an integrated package that emphasizes not only overall preconception care but, broadly, women's health (141). For preconception care in particularly a helpful guiding concept is the 12-month pregnancy, which includes also the trimester *before* conception. This preconceptional period, together with at least the first 2 months of pregnancy, provides a crucial opportunity for promoting healthy cardiac development. Much of cardiac development occurs in the first 7 weeks postconception, at a time that many women may be unaware of the pregnancy, potentially exposed to teratogens, and with limited or no prenatal care. On an individual basis, crucial areas of counseling include screening and managing chronic illnesses or exposures, avoiding exposures to acute illnesses, alcohol and smoking, and taking a daily multivitamin containing folic acid. On a population-basis, effective strategies will have to consider an integrated education campaign for women and providers on common or highly preventable risk factors, increasing access to preconceptional and prenatal care, and reducing disparities in access and care.

Tools

For these interventions, specific tools can be very helpful. Some tools and materials can be found in ongoing prevention initiatives such as "power your life" (319) and through local agencies and organizations. For the busy clinician who wants to promote primary prevention in daily clinical practice, a screening questionnaire could be a helpful adjunct tool to identify major areas for referral or intervention. One possible model (320) is illustrated in Figure 25.20.

Such tools, used regularly ("every woman, every time"), can serve as reminders, as screening tools that can lead to referrals or further management, and as prompts for education.

CONCLUDING COMMENTS

Significant data gaps remain in our understanding of outcomes, risk factors, and best strategies for preventions. However, currently available data is already sufficient to begin a concerted effort to prevent congenital heart defects. Effective prevention requires a combination of incentives that drive policy, evidence based on science, strategies to maximize the effect of interventions, and tools to make these interventions

Additional comments (add a page if needed):

Figure 25.20. Sample questionnaire to screen for common modifiable risk factors for congenital heart defects in clinical practice.

practical, sustainable, and consistent. Epidemiology provides much of the supporting data, from assessing the impact of congenital heart defects (from prevalence to mortality to cost) to evaluating the effects of intervention (by ongoing monitoring of outcomes and risk factors).

In the real world, prevention requires an integrated and sustained effort by the clinical, research, and public health community. This task ought to be tackled with a sense of urgency. Research into new causes and genetic determinants of congenital heart defects needs to go on, to fill the considerable data gaps that still exist on the etiology of heart defects. Yet, even in this stage of incomplete knowledge, some aspects of prevention can and should be implemented today. Pregnancies exposed to known teratogens such as diabetes continue to occur, and affected children continue to be born. To change this, it will be crucial not only to target individual women for preconceptional education and care but also to sustain population-wide interventions that ensure a fair and equitable change for prevention for all groups in the population, so that the benefits of prevention can accrue to all, regardless of education or means.

Since the publication of this chapter in the seventh edition of this book, there has been ongoing progress in both the medical and surgical management of children born with congenital heart defects (CHDs) and the genetic technology that has assisted diagnosis, management, and research. Patients with significant heart disease now routinely survive well into adulthood. With these advances come new questions about variability in clinical outcome, long-term survival, fetal intervention, and recurrence risk. Although differences in clinical management affect clinical outcome and survival, evidence suggests that the etiologic basis of these malformations contributes to outcome as well (1–4). These observations highlight the importance of understanding the causes of CHDs.

Environmental, genetic, and stochastic factors contribute to the cause of CHDs (Table 26.1) (5,6); an expanded discussion of environmental risk factors and teratogens can be found in Chapter 25. Evidence for a genetic contribution comes from several observations. First, specific types of CHDs are commonly seen with specific chromosomal abnormalities. For example, atrioventricular septal defects are most commonly diagnosed in patients with trisomy 21, and patients with trisomy 21 are commonly diagnosed with atrioventricular septal defects. Second, similar CHDs can occur in multiple members of a family, suggesting a genetic basis. Recent studies have demonstrated particularly high heritability in certain subsets of CHDs such as left-sided lesions (7–9). Third, epidemiologic studies demonstrate an increased precurrence and recurrence risk for CHDs in families with one affected member (10–13).

These observations also suggest that many CHDs result from complex genetic and environmental interactions rather than simple mendelian inheritance. Although the vast majority of patients with Down syndrome have a complete third copy of chromosome 21, only 40% to 50% of patients have CHD. In contrast to the consistent finding of intellectual disability, the less frequent expression of CHDs suggests that other genetic and/or environmental factors contribute to the risk of CHDs even in the presence of a major chromosomal alteration. Similarly, the likelihood that parents with one child affected with a nonsyndromic CHD will have a second affected child is increased as compared to the baseline risk in the general population, but the recurrence risk is significantly lower than simple mendelian inheritance would predict.

The heterogeneous etiologic factors of CHDs make it more difficult to understand the basis of these disorders. For example, several different genetic alterations are now known to be associated with tetralogy of Fallot including trisomy 21, the 22q11.2 deletion, and *JAG1* mutations (Table 26.1 and see below: Genetics of Specific CHDs). Tetralogy of Fallot is found in many other genetic syndromes and can be associated with maternal exposure to retinoic acid and maternal phenylketonuria (14). Therefore, defining the genetic alterations that contribute to the cause of specific CHDs and identifying those that affect clinical outcome is challenging.

Notable advances have begun to unravel the genetic basis of these disorders. The first edition of this text published in 1968 cited 15 genetic syndromes and conditions, including storage diseases (personal correspondence from Dr. George Emmanouilides, Harbor-UCLA Medical Center). More than 50 years later, this chapter lists 50 of the most familiar or distinctive malformation syndromes characterized in part by CHDs and associated with an identifiable cause. As discoveries are made, the number of children with defined genetic causes of their CHD will increase. The information should help the physician counsel families more accurately about recurrence risks and clinical outcome and, it is hoped, lead to novel medical therapeutics to improve clinical outcomes. Since rapid progress is likely to continue, the medical caregiver will need a firm understanding of this area to anticipate its impact on clinical medicine.

This chapter reviews the genetic basis of CHDs by providing sufficient fundamental concepts to give readers a consistent background, yet remaining a pragmatic “off-the-shelf” handbook in real clinical and educational settings. The term CHDs refers to developmental changes of the intracardiac structures and major vessels and is interchangeable with the terms cardiovascular malformation or congenital heart disease. The genetic basis of cardiomyopathies and arrhythmias, both of which may be associated with a CHD, is discussed in other chapters. Instead of listing all possible genetic syndromes associated with each CHD (which can be found in multiple online and textbook resources listed below), this chapter presents an alternative approach for considering the genetic causes of CHD, ordered by genetic mechanism to help the reader understand and anticipate future developments in this field. In addition, Tables 26.2–26.4 summarize the growing number of syndromes that are either common conditions frequently associated with any type of CHD, or uncommon syndromes associated with a distinctive pattern of CHD. The chapter concludes with suggested guidelines for the genetic evaluation of a child with a CHD.

METHODS AND MECHANISMS

Genetic Testing

In large part, the identification of novel genetic abnormalities associated with disease has been driven by increasingly sensitive methods to detect genetic alterations. The technology to detect structural variation in the human genome (134) has progressed from microscopic to genomic analyses, and is of interest to both clinician and researcher. In the first era of chromosome analysis, the *karyotype* displayed the 23 pairs of human chromosomes and detected changes in chromosome number (such as trisomy 21) or large changes in chromosome architecture such as translocations (the exchange of pieces between two chromosomes). Smaller changes such as

TABLE 26.1 Causes of CHDs

Etiology	Example: Patient with Tetralogy of Fallot (TOF)
Chromosomal change	
Change in chromosome number	Trisomy 18 or 21
Translocation between chromosomes	Translocation 1p36
Deletion of chromosome segment	Deletion 5p or 22q11.2
Duplication of chromosome segment	Partial trisomy 8q
Single gene or gene pair abnormality	
Isolated CHD	Newborn with TOF, whose mother also had TOF repaired in childhood; sister has malalignment-type VSD (probable autosomal dominant inheritance)
Associated with syndrome	<i>JAG1</i> mutation in Alagille syndrome
Mitochondrial defect	None known
Environmental exposure	Fetus found to have TOF, mother known to have maternal phenylketonuria
Multifactorial causation (gene/environmental interaction)	TOF in a child with ectopia cordis
Stochastic events	Isolated TOF

VSD, ventricular septal defect.

a visible *deletion* or *duplication* of chromosomal segments were subsequently detected by new “banding” methods, such as Giemsa staining, which resulted in characteristic dark and light bands for each chromosome. More recently, *fluorescence in situ hybridization* (FISH), multiplex ligation-dependent probe amplification (MLPA), and microarray technologies have been used to detect smaller deletions and duplications of chromosome segments that could not otherwise be seen on a standard or even high-resolution karyotype. Identification of disease-related *mutations* or alterations in the genetic code for a single gene can be detected using various techniques.

Accordingly, changes in chromosome number such as trisomy 21 or Turner syndrome were among the first identified genetic causes of CHDs. Deletion syndromes such as the 22q11.2 deletion or Williams syndromes were subsequently recognized with the advent of new banding techniques and then FISH, MLPA, and now microarrays. The advent of microarray technology has also permitted the characterization of an increasing number of deletion and duplication syndromes such as 1p36 deletion and 8p23 deletion syndromes (Table 26.2) (135,136). Given the ability of microarrays to survey the entire genome for changes in regional chromosomal imbalances, this technology has become the test of choice in many scenarios and centers (137).

Increasingly automated mutation detection and gene sequencing techniques now identify disease-related mutations in single-gene disorders such as Holt-Oram or Alagille syndromes. The growing ability to identify disease-related mutations by gene sequencing has allowed additional clinical genetic testing in individual patients or families.

Investigative Approaches

Investigators have used a variety of approaches to identify the genetic cause of CHDs reflecting advancements made in

molecular genetic technologies. Historically, the identification of a consistent chromosomal alteration on a karyotype focused where investigators might look for the genetic basis of that disease. For example, 5% to 10% of patients with Alagille syndrome were originally noted to have a chromosomal deletion involving the “p” (short) arm of chromosome 20 (see Alagille syndrome). This observation suggested that other patients might have submicroscopic alterations of that region or a mutation in a gene in that region. Further investigations found disease-causing mutations in a gene called *JAG1* that mapped into the region of 20p, thereby establishing *JAG1* as one of the disease genes for Alagille syndrome.

Alternatively, large kindreds with multiple affected members permit a parametric linkage analysis to map the disease gene to a chromosomal position or locus. Informative linkage analyses were responsible for identifying the disease genes in Marfan, Holt-Oram, and Noonan syndromes as well as familial cases of atrial septal defect with atrioventricular conduction blockade (*NKX2.5*), to name a few (see in Single-Gene Disorders). The Human Genome Project has greatly simplified and accelerated the identification of disease genes once a disease locus is defined.

These aforementioned strategies to identify disease-related genes are limited by the relative rarity of large kindred or consistent chromosomal changes. However, emerging chromosome microarray technologies have identified an increasing number of previously unrecognized submicroscopic chromosomal deletions and duplications, thereby defining new genetic syndromes and disease genes (135–138). The advent of “next generation sequencing,” including large-scale gene, whole exome, and whole genome sequencing, promises to identify an increasing number of disease-causing variants as well.

As noted, it is increasingly apparent that a large proportion of CHDs are complex in origin, resulting from a combination of genetic and environmental risk factors in any one patient or family (5,6,13). Studies to date suggest marked genetic heterogeneity in the number of disease genes associated with any one

TABLE 26.2 Chromosome Abnormality Syndromes Associated with CHDs

Syndrome	Reference	Gene(s) ^b	OMIM No.	Frequency of CHD ^a		Distinctive Features ^c
				All (%)	Distinctive or Common	
Changes in chromosome number						
Trisomy 13	(15–17)			50–80	Conotruncal CHDs: DORV, TOF VSD, ASD, PDA AVSD Polyvalvar dysplasia	Polydactyly Cleft lip and palate CNS anomalies (holoprosencephaly) Renal, GU anomalies Scalp cutis aplasia Microphthalmia
Trisomy 18	(15,16,18–21)			95	Polyvalvar dysplasia Conoventricular VSD TOF, DORV AVSD	Overlapping fingers CNS anomalies (posterior fossas) Small facial features Rocker bottom feet Renal, GU anomalies
Down syndrome (trisomy 21 most common)	(22–24)		190685	40	AVSD defects: Complete AVSD Primum ASD VSD, all types Secundum ASD PDA TOF	GI anomalies Endocrine anomalies Fifth finger clinodactyly Leukemoid reaction Microbrachycephaly
Turner syndrome (45,X most common)	(25–32)			25	LVOTO CHDs: BAV ± AS(V) Coarctation MV anomalies, MVP PAPVC, LSVC Aortic dilation, dissection Hypertension Prolonged QTc	Horseshoe kidney Short fourth metacarpal Neck webbing Lymphedema Infertility Short stature Nevi, keloids Hypothyroidism
Chromosome deletion or duplication

^aFrequency figures rounded. When not specified in an article, data were calculated independently. Congenital heart “defects” excluded valve regurgitation, patent foramen ovale, and unspecified murmur, cyanosis, or heart disease. Some syndrome-specific nonstructural anomalies were included.

^bGenes listed map to the disease locus and are specifically associated with the cardiovascular features of the syndrome, though other genes in the chromosomal region may also be related to the syndrome.

^cMost syndromes have growth delay, some degree of developmental delay/mental retardation, and dysmorphic facial features, which can be reviewed in general genetics references (72,73).

^dFrequency reflects cases with molecular confirmation.

ASCA, aberrant subclavian artery; ASD, atrial septal defect; AS(V), aortic stenosis (valvar specified); AVSD, arterioventricular septal defect; BAV, bicuspid aortic valve; CHDs, congenital heart defects; CNS, central nervous system; DCM, dilated cardiomyopathy; DDRV, double-outlet right ventricle; FAVS, facioauriculovertebral spectrum; GI, gastrointestinal; GU, genitourinary; HCM, hypertrophic cardiomyopathy; HLHS, hypoplastic left heart syndrome; IAA, A/B, interrupted aortic arch, type A or B; LSVC, left superior vena cava; LVOTO, left ventricular outflow tract obstruction; MS, mitral stenosis; MVP, mitral valve prolapse; OMIM, on line Mendelian inheritance in man; PA, pulmonary atresia; PAPVC, partial anomalous pulmonary venous connection; PDA, patent ductus arteriosus; (P)PS, (peripheral) pulmonic stenosis; PS(V), pulmonary stenosis (valvar specified); RVOTO, right ventricular outflow tract obstruction; TAVPC, total anomalous pulmonary venous connection; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

lesion, and identify a wide range of genetic alterations ranging from whole chromosome to single nucleotide changes. The extent to which common and/or rare variants, be they single nucleotide polymorphisms (SNPs), deletions, or duplications, contribute to disease risk is a subject of much debate and investigation. In either case, defining disease-associated genetic variants, genes, and developmental pathways provides new opportunities for novel therapeutic and preventive strategies.

PATTERNS OF INHERITANCE AND FAMILIAL RISKS

Assessing the risk of recurrence (the chance that an affected parent will have an affected child or that unaffected parents will have a second affected child) for a patient or their relative is an ongoing challenge (139). Historically, different study designs, variable classification schemes of CHDs, different modes of ascertainment, and evolving methods of diagnosis have made it difficult to compare studies and have complete confidence in the results. Most cases of CHD have been thought to be sporadic. Overall, low recurrence risks of 2% to 4% have been quoted for all types of CHDs with one affected sibling or parent (140–143). Studies suggest that the recurrence risk increases if more than one sibling is affected (13) although it has been unclear if an affected mother confers a greater risk than an affected father (144,145). Recurrent CHDs within a family are often concordant or derive from the same class of defects (140).

Data from these studies are valuable, but must be used with some caution. Earlier studies did not consider the more recently described mendelian syndromes and chromosomal

causes of CHDs, factors that affect the overall recurrence frequency. In addition, familial cases of almost every type of CHD have been observed as has every pattern of inheritance including autosomal dominant, autosomal recessive, X-linked, or complex nonmendelian patterns of inheritance. The observed pattern of inheritance greatly influences the risk of recurrence for any one family and must be considered for counseling purposes.

As an alternative to recurrence risk analysis, investigators from the Baltimore-Washington Infant Study calculated the rate of CHD precurrence (the number of currently affected relatives at the time of birth) (10). Their studies demonstrated increased familial disease, especially left-sided CHDs. Left-sided obstructive defects have also been the subject of several recent large family studies. Echocardiography was performed on first-degree relatives of probands to complement extensive pedigree analysis and better assess the occurrence of CHD in each family. These reports found that 8% to 19% of first-degree relatives of patients with left-sided CHDs had predominantly concordant CHDs, suggesting that left-sided CHDs commonly result from inherited genetic traits (7–9,146). Of note, CHDs were identified with higher frequency in first-degree relatives of probands with hypoplastic left heart syndrome (HLHS) (19.3%) and coarctation of the aorta (9.4%) than in first-degree relatives of probands with D-transposition of the great arteries (2.7%) (9). Most recently, several studies confirm high heritability of left-sided CHDs (implying a strong genetic component to their etiology) and marked genetic heterogeneity with evidence for possible autosomal dominant inheritance in some pedigrees (7,146–149). Studies detailing the heritability of other types or classes of CHDs have not yet been performed to provide similar data.

TABLE 26.3 Single-Gene Disorders Associated with CHDs

Syndrome	Reference	Gene(s)	OMIM No.	Frequency of CHD ^a		Distinctive Features ^b

See Table 26.2 for definition of abbreviations.

^aFrequency figures rounded. When not specified in an article, data were calculated independently. Congenital heart “defects” excluded valve regurgitation, patent foramen ovale, and unspecified murmur, cyanosis, or heart disease. Some syndrome-specific nonstructural anomalies were included.

^bMost syndromes have growth delay, some degree of developmental delay or mental retardation, and dysmorphic facial features, which can be reviewed in general genetics references (72,73).

^cFrequency reflects cases with molecular confirmation.

TAPVR, partial anomalous pulmonary venous return; TAPVR, total anomalous pulmonary venous return.

(Adapted from Lin AE, Belmont J, Malik S. Heart. In: Stevenson RE, Hall JG, eds. *Human Malformations and Related Anomalies*. 2nd ed. New York, NY: Oxford University Press, 2006:85–120; Lin AE, Ardinger HH. Genetic epidemiology and an overview of the genetics of congenital heart defects. *Prog Pediatr Cardiol* 2005;20:113–126, Ref. 119.)

Collectively, these findings suggest that precurrence and recurrence rates are likely to vary between specific types of CHD and within different kindred. Therefore, instead of using population-based empiric data alone, counseling for recurrence risk for an individual family requires the consideration of multiple factors including the specific type of CHD, the presence of additional affected family members, and the presence of known genetic or syndromic risk factors.

GENETIC SYNDROMES

Genetic syndromes are defined as a consistent pattern of malformation caused by a genetic alteration. A malformation syndrome consists of multiple structural defects that are thought to be due to a single cause, even if the suspected cause has not yet been identified (72). The cause can include genetic alterations such as changes in chromosome number, translocations

between chromosomes, deletions or duplications of specific chromosomal regions, or single-gene defects, or can involve a teratogen (Table 26.1). The most common genetic syndromes are described in the following sections organized by the type of associated genetic alteration. For each syndrome the genetic basis, clinical and cardiac phenotype, diagnostic testing, natural history, and population frequency are described. A more extensive table of syndromes is provided for reference (Tables 26.2–26.4). In addition to the common conditions summarized in this chapter, there is a constantly enlarging compendium of chromosome regions associated with CHDs that have evolved from cytogenetically visible aberrations (150,151) to complex genomic-based networks (152). Genetic textbooks, chapters, and online services provide extensive descriptions of each syndrome (72,73,153,154). An alternative listing of syndromes by cardiac subclasses may be more practical for the cardiologist searching for information based on the specific type of heart defect, especially when a dysmorphic child lacks a specific syndromic diagnosis (118).

Syndromes Associated with Chromosome Abnormalities

In population-based studies, a chromosome abnormality was detected in approximately 13% of children in the first year (22,155), and in 19% to 36% of miscarriages and stillborn fetuses with a cardiac defect (156). These occurrence data are reviewed in more detail in Chapter 25 of this text. Chromosome abnormalities can be classified according to an increase or decrease in whole chromosome number (aneuploidy), an increase or decrease of part of a chromosome (duplication or deletion, partial trisomy, or partial monosomy), or a more complex rearrangement. More recently, chromosome microarray analysis may be able to detect a causal diagnosis in up to 18% with a “syndromic CHD” (157). Of the many possibilities, Table 26.2 lists the most common syndromes with the most distinctive CHDs, with selected ones discussed below.

Change in Chromosome Number (Aneuploidy)

Down Syndrome

The most familiar syndrome to cardiologists is Down syndrome in which there is trisomy 21 in 94% (a complete extra copy of chromosome 21) (Table 26.2). Less commonly, (6% overall), partial trisomy of chromosome 21 is present owing to a chromosomal translocation or mosaicism. The well-known facial appearance changes with age and varies with ethnic background (Fig. 26.1). Common findings include hypotonia, global developmental delays and moderate intellectual disability, microbrachycephaly, small ears, mouth and nose, protruding tongue, upslanting eyes with epicanthal folds, transverse palmar creases, and sparse hair. Skeletal anomalies include fifth finger clinodactyly, brachydactyly, a gap between first and second toes, atlantoaxial instability, hypoplastic pelvis, and joint laxity. Additional problems involve the visual, auditory, endocrine, hematologic, reproductive, and gastrointestinal systems.

Almost half of liveborn Down syndrome individuals have a CHD, approximately 40% of whom have a complete atrioventricular septal defect (also known as atrioventricular canal defect or endocardial cushion defect) (23). When primum-type atrial septal defect, canal-type ventricular septal defect, and transitional atrioventricular septal defect are included, the frequency of the atrioventricular family of septal defects increases to almost 60% (22–24). The association of Down syndrome and atrioventricular septal defects is underscored by the fact that approximately 75% of patients with a complete atrioventricular septal defect have Down syndrome. Other common CHDs include secundum atrial septal defect, perimembranous and muscular ventricular septal defect, tetralogy of Fallot (with and without atrioventricular septal defect), and hemodynamically significant patent ductus arteriosus.

Mothers older than age 35 years have an increased risk of conceiving a child with aneuploidy (an extra chromosome), including Down syndrome. Cross-sectional data (1979 to 2003) looking at Down syndrome children aged 0 to 19 years in 10 sections of the United States showed a steady increase from 9.0 to 11.8 per 10,000, but was lower among non-Hispanic blacks (158). Overall survival has improved, although prenatally diagnosed CHDs and/or growth retardation may predict a poorer outcome (159). The median age at death increased from 25 to 49 years in the interval from 1983 to 1997 (160). Equivalent if not better surgical results for atrioventricular septal defect repair with similar postoperative residual cardiovascular defects have been reported in Down as compared with non-Down syndrome individuals (161,162).

The largest survey study to date reported that the frequency of CHDs in patients with Down syndrome mosaicism was

Figure 26.1. Down syndrome. A thriving 1-year-old girl with epicanthal folds, small nose, small mouth, small ears, and atrioventricular septal defect. (Courtesy of Sara S. Halbach, MS, CGC; Donna McDonald-McGinn, MS, CGC; Terri Anderson, MD; and Elaine Zackai, MD, The Children's Hospital of Philadelphia.)

similar to the complete trisomy 21 comparison group (~42% and 50%) (163). Atrial septal defect was the most common CHD, with atrioventricular septal defect reported in 11% compared to 22%.

The strong association of Down syndrome and atrioventricular septal defects prompted a search for a cardiac gene on chromosome 21. A Down syndrome critical region on chromosome 21 (21q22) and CHD candidate genes have been proposed, although causation for atrioventricular septal defects has not been demonstrated (164).

The only source of data on Down syndrome adults followed postoperatively (165) recommended monitoring as with any child who had a similar CHD repair. Conduction block with variable escape arrhythmia should be assessed with periodic Holter monitoring.

Trisomy 18

Although most fetuses with trisomy 18 may not survive until livebirth, there are many parents who will seek aggressive support for these seriously affected children, and thus, clinicians should be familiar with their appearance and CHDs (18). These children have short palpebral fissures, small mouth, micrognathia, growth retardation, prominent occiput, clenched hands, disorganized or hypoplastic palmar creases, hyperconvex nails, short sternum, small nipples, radial deficiency, and anomalies of almost every organ system.

CHDs are nearly ubiquitous and include perimembranous ventricular septal defect, tetralogy of Fallot, double-outlet right ventricle, and polyvalvar dysplasia in which two or more valve

leaflets are thickened, myxomatous, or dysplastic (15,19,20). A natural history study of trisomy 18 in the United Kingdom reported that the prevalence at 18 weeks' gestational age was about 1 in 4,000, which decreased to 1 in 8,000 at birth (21). Recent population-based analyses of trisomy 18 (and trisomy 13) born during 1968 to 1999 reaffirmed that the vast majority (91%) die in the first year of life, although CHDs did not seem to affect survival (16). Although the high lethality and obligatory severe mental retardation among survivors is well recognized, some parents of trisomy 18 infants advocate for cardiac surgery, among other procedures.

There is no single trisomy 18 critical region. Instead, analysis of individuals with duplication of distal 18q provides insights into chromosome regions that may contribute to the trisomy 18 phenotype (166).

Turner Syndrome

The liveborn prevalence of Turner syndrome is approximately 1 per 2,000 (167). The phenotype depends on whether the X chromosome is absent (45,X in almost 50% of patients) or structurally abnormal (168). The most common presentation is a spontaneously aborted fetus with hydrops or lymphatic malformation in the neck or mediastinum. Fetal lymphedema produces neck webbing, protruding ears, low hairline, puffy hands and feet, and deep-set nails (Fig. 26.2). Frequent findings include short fourth metacarpals, cubitus valgus, Madelung deformity, osteoporosis, kyphoscoliosis, broad chest with apparently widely spaced nipples, renal anomalies (horseshoe kidney), nevi, hearing loss, infertility, autoimmune diseases, as well as deficits in visual-spatial/perceptual abilities, attention, and social skills. Turner syndrome women with 45,X generally have more malformations as compared to those with only partial deletion of the X chromosome. Mosaicism involving 45,X/46,XX is usually associated with a milder phenotype, and 45,X/46,XY mosaicism increases the risk for gonadoblastoma (168).

Approximately 30% of Turner syndrome women have a CHD, which usually involves the left-sided cardiac structures (25,26,168), and up to 50% of adults have vascular anomalies

Figure 26.2. Turner syndrome. An 11-year-old girl with hyperlordism, facial nevi, and dysplastic right pinnae. She has short stature, normal intelligence, thyroiditis, and no CHDs. (Courtesy of Angela E. Lin, MD.)

detected by magnetic resonance imaging (MRI) (27,169). An asymptomatic bicuspid aortic valve (15%) may progress to aortic stenosis (10%), and coarctation of the aorta (with or without a bicuspid aortic valve) is present in 10% of Turner syndrome patients. Because these findings are significantly associated with the presence of neck webbing, investigators have hypothesized that the altered lymphatic drainage itself causes the associated left-sided obstructive lesions (26,170). It is unproven whether haploinsufficiency for genes on the X chromosome that may impair lymphatic and vascular development represent the underlying cause instead (28). Less common left-sided defects include elongation of the transverse arch and/or pseudocoarctation (almost half of adults with Turner syndrome) (27), various mitral valve anomalies (<5%), and HLHS (rare). Secundum atrial septal defect, perimembranous ventricular septal defect, partial anomalous pulmonary venous connection often involving the upper left pulmonary vein, and persistent left superior vena cava also occur, but complex CHDs, especially conotruncal defects, are noticeably rare (25–27).

Turner syndrome women are at risk for aortic dilation, dissection, and sudden death. Prospective MRI of older patients doubles the echocardiographic detection of aortic dilation (33% vs. 16%) (169). Arterial dilation and arterial wall abnormalities, and cerebral involvement suggest that there may be a more diffuse vasculopathy (171,172). An epidemiologic description of aortic dissection calculated a sixfold population-based risk (36 per 100,000 Turner syndrome years), or an approximate 1.4% risk (29). Aortic dissection in Turner syndrome is almost always associated with a risk factor such as bicuspid aortic valve, coarctation of the aorta or hypertension; the few individuals without an underlying cause may reflect inadequate examination (173,174), although an intrinsic predisposition cannot be excluded. Consensus guidelines (28) for the increasing number of older women with Turner syndrome include baseline imaging of the aorta at the time the condition is diagnosed and ongoing blood pressure monitoring. MRI may provide superior images to echocardiography depending on age, coexisting CHDs, previous surgery, and body habitus (27,169). Repeat imaging should be done every 5 to 10 years, with the appearance of hypertension, or if pregnancy is contemplated (28,175). In general, growth hormone does not appear to promote aortic dilation (30,31). A disturbing number of deaths owing to aortic dissection raises concern about the safety of pregnancy (175,176). For the increasing number of women who consider pregnancy using assisted reproductive technology with oocyte donation, it seems prudent to exclude the women who have risk factors for dissection, and plan pregnancy according to guidelines published in 2007 (28).

Adult women with Turner syndrome require monitoring for postoperative recoarctation and hypertension, and aortic stenosis and regurgitation. Unrepaired bicuspid aortic valve should be monitored for the development of progressive stenosis and aortic dilation. Hypertension and coronary artery disease are more common than in the general population (174,177). Prospective electrocardiogram (ECG) monitoring may also be indicated since data demonstrate conduction and repolarization abnormalities (including prolongation of the QTc interval) (32).

Studies correlating genotype with clinical phenotype suggest that haploinsufficiency of the short stature-homeobox gene on the short arm of the X chromosome leads to short stature and skeletal changes. Genes on both arms of the X chromosome are important for ovarian function. However, there is no known critical region on the X chromosome for CHDs.

Deletion–Duplication Syndromes

Microarray technologies have markedly increased the ability to detect chromosome imbalances along the entire length of

the chromosome, and as such have often become the test of choice to detect deletions and duplications (137). As a result of these rapid technologic advancements, an increasing number of small chromosomal deletions and duplications that are not apparent on a high-resolution karyotype have been identified in patients with various clinical syndromes and multiple congenital anomalies. A chromosomal *deletion* occurs when there is a missing segment of a chromosome on one of the two copies of the same chromosome resulting in one copy, or haploinsufficiency, of that region (partial monosomy). Conversely, a chromosomal *duplication* occurs when there is an extra copy of one segment of a chromosome resulting in three copies of that region (partial trisomy). Research has defined an expanding list of deletion and duplication syndromes over the last decade. Most of these syndromes are characterized by multiple congenital anomalies, presumably because of the number of genes involved in the deleted or duplicated segments. They also display marked clinical variability between individuals. Many of these syndromes are associated with CHDs and thus constitute an increasingly important group of syndromes with which a cardiologist should be familiar. Examples of the most common deletion syndromes with cardiovascular features are described below, and others are highlighted in Table 26.2.

The 22q11.2 Deletion Spectrum (DiGeorge Syndrome, Velocardiofacial Syndrome)

Molecular studies demonstrate that the vast majority of patients with the clinical diagnosis of DiGeorge, velocardiofacial (Shprintzen syndrome), or conotruncal anomaly face syndromes share a common genetic cause, namely, a 22q11.2 deletion (178–180). The 22q11.2 deletion syndrome is currently the most common deletion syndrome known and is estimated to occur in approximately 1 in 6,000 live births (155,181).

The clinical phenotype of the 22q11.2 deletion syndrome is highly variable among related and unrelated individuals (182). The presentation can be severe and easily recognized at birth or subtle and detected late in life. Approximately 6% to 10% of cases are familial, implying that the affected child inherited the chromosomal deletion from a parent. Frequently, the parent is recognized to carry a 22q11.2 deletion only after their more severely affected child is diagnosed. The most common features include CHDs, palate anomalies, feeding disorders, speech and learning disabilities, hypocalcemia, immunodeficiency, renal anomalies, behavioral and psychiatric disorders, and typical facial features (reviewed in Ref. 67) (Fig. 26.3). However, the facial features can be difficult to identify in infants and may be underappreciated in certain populations such as African Americans (183).

CHDs are estimated to occur in 75% to 80% of patients with a 22q11.2 deletion (68,69). The prevalence of CHDs may be overestimated because of increased ascertainment in the pediatric population with CHDs as compared with adults with more subtle features (184). The most common CHDs associated with a 22q11.2 deletion include tetralogy of Fallot, interrupted aortic arch type B, truncus arteriosus, perimembranous ventricular septal defect, and aortic arch anomalies (68,69). It should be noted that a wide range of CHDs has been reported in patients with a 22q11.2 deletion, including pulmonary valve stenosis, atrial septal defect, heterotaxy syndrome, and HLHS.

Because CHDs are common in the 22q11.2 deletion syndrome, several studies have estimated the frequency with which a 22q11.2 deletion is found in patients with CHDs typical of DiGeorge or velocardiofacial syndromes. At least 50% of patients with an interrupted aortic arch type B, 35% with truncus arteriosus, 24% with an isolated aortic arch anomaly, 15% with tetralogy of Fallot, and 10% with a perimembra-

Figure 26.3. 22q11.2 deletion syndrome. A 5-year-old boy with typical facial features of the 22q11.2 deletion syndrome including malar flattening, small mouth, bulbous tipped nose with hypoplastic alae nasi, and micrognathia. He also had tetralogy of Fallot, developmental delay, mild immune suppression, and late emergence of speech. (Courtesy of Donna McDonald-McGinn, MS, CGC; Elaine Zackai, MD; and Elizabeth Goldmuntz, MD, The Children's Hospital of Philadelphia.)

nous ventricular septal defect are found to have a 22q11.2 deletion (70,185–193). In contrast, <1% of patients with double-outlet right ventricle or D-transposition of the great arteries are found to have a 22q11.2 deletion. Several studies have demonstrated that patients with one of these intracardiac anomalies and a concurrent aortic arch anomaly (either abnormal sidedness, cervical location, or abnormal branching pattern) are more likely to have a 22q11.2 deletion. For example, only 3% of patients with a perimembranous ventricular septal defect and a normal left-sided aortic arch with normal branching pattern were diagnosed with the 22q11.2 deletion, whereas 45% with a perimembranous ventricular septal defect and concurrent aortic arch anomaly had a 22q11.2 deletion (192). Therefore, the presence of an aortic arch anomaly increases the risk of finding a 22q11.2 deletion regardless of the intracardiac anatomy. Studies also suggest that the subset of patients with tetralogy of Fallot associated with absent pulmonary valve syndrome or aortopulmonary collaterals are at higher risk of having a 22q11.2 deletion (191,194). Collectively, these findings demonstrate that a 22q11.2 deletion is commonly found in a significant subset of patients with congenital cardiovascular defects.

Identifying the cardiac patient with a 22q11.2 deletion early in life can provide substantial benefits to the child and family. Currently, it is recommended that infants with interrupted aortic arch type B, truncus arteriosus, tetralogy of Fallot, and isolated aortic arch anomalies undergo testing for a 22q11.2 deletion given the high frequency with which these patients are found to harbor a 22q11.2 deletion (5). Likewise, it is

suggested that patients with a perimembranous ventricular septal defect and aortic arch anomaly, or any infant with noncardiac features of the 22q11.2 deletion syndrome (regardless of the CHD) undergo 22q11.2 deletion testing. Although somewhat controversial, current recommendations for testing seek to identify the deletion-bearing patient as early as possible to anticipate associated medical conditions and provide accurate family genetic counseling. Parents found to carry the deletion have a 50% chance of transmitting the deletion-bearing chromosome in subsequent pregnancies.

Although the evaluation must be tailored to each patient's needs, infants or children diagnosed with the 22q11.2 syndrome should be evaluated for associated noncardiac features including hypocalcemia, immunodeficiency, palate anomalies, feeding and speech disorders, renal and skeletal anomalies, cognitive deficiencies, and behavioral issues (67). Parents should be tested for a 22q11.2 deletion as well. A 22q11.2 deletion is now easily detected using FISH, MLPA, or microarray technologies, though the latter is becoming the test of choice in many centers (137).

Many children present with noncardiac symptoms and are diagnosed with a 22q11.2 deletion later in infancy or childhood. Although these patients are unlikely to have major intracardiac anomalies, aortic arch anomalies are commonly identified in this subset of patients. In particular, 38% of patients diagnosed with a 22q11.2 deletion after 9 months of age were found to have an aortic arch anomaly, of whom 27% had a symptomatic vascular ring (195). A remarkable variety of aortic arch anomalies has been found in the 22q11.2-deleted population including absent or isolated subclavian arteries where retrograde flow through the vertebral artery provides flow into the absent or isolated subclavian artery predisposing to a steal phenomenon (196). Since respiratory symptoms including asthma and airway anomalies are commonly diagnosed in the 22q11.2-deleted population, it is important to identify which children have concurrent vascular rings contributing to or causing their respiratory symptoms and which should undergo surgical ligation.

Caring for the CHDs of adults with 22q11.2 deletions is similar to their nonsyndromic counterparts and lesion specific. Aortic root dilation has been observed in a subset of older children without CHD, but its clinical significance is not yet understood (197).

7q11 Deletion (Williams-Beuren Syndrome)

Williams-Beuren syndrome ("Williams syndrome") is another familiar multisystem disorder that occurs in 1 per 20,000 live-births. It is characterized in part by CHDs, hypercalcemia in infancy, skeletal and renal anomalies, cognitive deficits, social personality, and elfin facies (Fig. 26.4). As with other deletion syndromes, children with Williams syndrome can be diagnosed at different ages and present with a broad range of clinical features (reviewed in 206). Early in life, feeding disorders and growth retardation are common. Hypercalcemia is seen in 15% of infants and usually resolves over time (198). The neurocognitive profile of Williams syndrome most commonly includes mild mental retardation, although the full-scale IQ ranges from low normal intelligence to severe mental retardation. Cognitive strengths and weaknesses relative to other patients with mental retardation include relatively good auditory rote memory but extreme difficulty with visuospatial construction tasks (199). The familiar high sociability and overly friendly demeanor seen in some patients with Williams syndrome may be accompanied by substantial behavioral disorders, including inattention and hyperactivity.

Approximately 55% to 80% of patients with Williams syndrome have CHDs, which typically include supravalvar aortic stenosis and/or supravalvar pulmonary stenosis

Figure 26.4. Williams syndrome. A 17-month-old girl with typical facial appearance including flared eyebrows, bright stellate irides, and wide mouth. She has mild supravalvar aortic stenosis. (Courtesy of Amy E. Roberts, MD, Children's Hospital, Boston.)

(200,201). The degree of cardiovascular involvement and the relative involvement of the pulmonic or aortic vessels vary widely. Although supravalvar pulmonary stenosis usually improves with time, supravalvar aortic stenosis progresses in most cases (200,202,203). If significant supravalvar aortic stenosis is left untreated, cardiac hypertrophy followed by cardiac failure can result. Surgical and catheter interventions have met with success in some cases (204). Sudden cardiac death is another reported cardiovascular complication. Sudden death was described in 10 young children with Williams syndrome, seven of whom had coronary artery stenosis along with severe biventricular outflow tract obstruction (205). Presumably, sudden cardiac death resulted from myocardial ischemia, decreased cardiac output, and/or arrhythmias. Finally, patients with Williams syndrome may commonly develop hypertension either because of renal artery stenosis or other undefined mechanisms (201). Because of the generally diffuse arteriopathy and potential for hypertension, lifelong cardiovascular monitoring is recommended for patients with Williams syndrome (206).

Approximately 90% of patients with the clinical diagnosis of Williams syndrome have a deletion at chromosome 7q11.23, which is not generally apparent on a routine karyotype but can be detected by FISH, MLPA, and microarray technologies. Clinical testing is readily available in most standard cytogenetic clinical laboratories. Given the clinical variability of Williams syndrome, it is appropriate to consider testing all patients with supravalvar aortic or pulmonic stenosis for a 7q11.23 deletion.

Most patients with Williams syndrome have a 7q11.23 deletion of the same size. The genes mapping to this region have been defined and include the elastin gene, *ELN*. Mutations within the elastin gene have also been found in patients with isolated supravalvar aortic stenosis (207–209). Therefore, deletion of the elastin gene in patients with Williams

syndrome is thought to account for the cardiovascular phenotype. Molecular studies of rare patients with smaller deletions implicate the gene *LIMK1* in the impaired visuospatial constructive cognition (210). Additional genes mapping into the deleted region are thought to contribute to the neurocognitive features and are under further study. In contrast to the 22q11.2 deletion syndrome, these findings suggest that Williams syndrome is a true contiguous gene deletion syndrome in which the deletion of specific genes corresponds to distinct clinical features.

Studies further suggest that specific types of mutations in the elastin gene result in different clinical syndromes. As noted, a 7q11.23 deletion results in complete loss of one copy of the elastin gene (as well as other genes) and the diffuse arteriopathy seen in Williams syndrome. Disruption or mutation of the elastin gene alone can also result in isolated forms of supravalvar aortic and pulmonic stenosis. Both sporadic cases of supravalvar aortic stenosis and families with autosomal dominant inheritance have been found to have intragenic elastin gene mutations that result in functional hemizyosity (half of the functional gene dosage), similar to deletion of the entire gene (209). Mutations in the elastin gene have been identified in some patients with the autosomal dominant form of cutis laxa, another connective tissue disorder characterized by loose, saggy, inelastic skin. Both autosomal recessive and dominant forms have been observed in this genetically heterogeneous disorder (211,212). Studies suggest that these elastin mutations are functionally distinct from those associated with the diffuse arteriopathy, acting instead as a dominant negative effect. Thus, the specific elastin gene mutation appears to correlate with a specific clinical phenotype. These findings serve to demonstrate the complexity and heterogeneity of even seemingly straightforward genetic syndromes.

Emerging Microdeletion/Microduplication Syndromes

The advent of microarray technologies demonstrated that the human genome exhibits enormous variability both at the level of single nucleotides (so-called SNPs) and large segments of deoxyribonucleic acid (DNA) (deletions and duplications, or so-called copy number variants) (134). These technologies have provided increasingly sensitive means by which to identify cytogenetically undetectable changes in chromosomal copy number, and have therefore been used to identify new potential CHD disease loci. Several studies identify different copy number variants in cardiac patients, particularly in those with multiple congenital anomalies and/or developmental delay (157,213–216). Depending upon the resolution of the array, in these studies nearly 20% of such patients are found to harbor unique or rare copy number variants, though the disease significance of such findings in some cases remains to be demonstrated. These studies nonetheless highlight the potential clinical relevance of screening for submicroscopic alterations. In addition, several new deletion and duplication syndromes have been described, while others are just coming to be recognized. A subset of such syndromes are noted below, though further clinical testing and research will likely identify novel changes and solidify the significance of others.

11q23 Deletion Syndrome (Jacobsen Syndrome)

The 11q terminal deletion syndrome, previously known as Jacobsen syndrome, is thought to be a contiguous gene disorder characterized by distinctive facial features (Fig. 26.5), thrombocytopenia, developmental delay, CHD, short stature, genitourinary anomalies, pyloric stenosis, and ophthalmologic issues. As with other deletion syndromes, the clinical phenotype is highly variable, as is the size of the associated deletion. In a recent study (58), 56% of cases had serious CHDs, of

Figure 26.5. Jacobsen syndrome. An 18-year-old man with a deletion 11q23 (Jacobsen syndrome) who has mild features including short stature, mild intellectual disability, wide-spaced small eyes with mild ptosis, and small ears. (Courtesy of family.)

which approximately one-third had ventricular septal defects, one-third had left-sided anomalies (mitral and aortic valve), and one-third had a range of other types of CHD. Molecular analysis of 110 patients identified potential critical regions for multiple phenotypes. Though a rare diagnosis, it is an area of active research as further molecular analysis may identify specific disease-related genes, and current genetic testing methods may permit the identification of additional cases.

8p23.1 Deletion Syndrome

Numerous patients with interstitial or terminal deletions of 8p23.1 deletion have been reported. In general, such patients are characterized clinically by growth impairment, developmental delay, behavioral problems, microcephaly, diaphragmatic hernia, hypospadias, and CHDs (reviewed in Refs. 47 and 48). The most common CHDs include atrioventricular septal defects, atrial septal defects, ventricular septal defects, and pulmonary valve stenosis. The disease gene, *GATA4*, is often disrupted by these deletions, but cases with a *GATA4* deletion without CHD, as well as cases whose deletion does not encompass *GATA4* but have CHD, have been reported. Other genes disrupted by the deletion have also been implicated, but further studies correlating genotype with phenotype are warranted. More common use of clinical diagnostic array technology will likely identify an increasing number of cases with an 8p23.1 deletion.

1p36 Deletion Syndrome

Monosomy 1p36 is now recognized to be the second most common deletion syndrome with an estimated prevalence of 1 in 5,000 to 10,000 livebirths (33,34). As with other deletion

syndromes, the associated clinical phenotype is variable but notable for characteristic craniofacial features, ocular malformations or visual problems (52%), hearing loss (47%), neurologic abnormalities (44%), skeletal anomalies (41%), renal anomalies (22%), as well as CHDs (71%) (33). The most common CHDs include atrial septal defects, ventricular septal defects, patent ductus arteriosus, valve anomalies, tetralogy of Fallot, and coarctation of the aorta. Of note, many patients with 1p36 deletion syndrome present with cardiomyopathy including noncompaction of the left ventricle or dilated cardiomyopathy. One report described a patient presenting as an adult with noncompaction of the left ventricle, suggesting that lifelong observation for such complications might be warranted (35). As larger patient cohorts are identified with the 1p36 deletion syndrome, the prevalence of CHDs and cardiomyopathy will be better defined.

Genetic Syndromes Caused by Mutations in Single Genes

An increasing number of malformation syndromes has been found to be caused by a mutation of a single gene in contrast to a larger chromosomal abnormality (see Table 26.3). These mutations can be inherited in a mendelian fashion and demonstrate an autosomal dominant pattern of inheritance in families, with a 50% risk of recurrence. As with larger chromosomal alterations, single-gene disorders are characterized by a variable phenotype between related and unrelated affected individuals, suggesting that additional genetic and environmental factors modify the clinical phenotype of any single mutation.

The type of intragenic mutation may be variable (as in Alagille syndrome) or fairly consistent (as in achondroplasia) and may include nonsense, frameshift, missense, or splice site mutations. Specific mutations may result in different biologic consequences and may cause different clinical phenotypes (*variable expression*); mutations in different genes can produce a similar clinical phenotype (*genetic heterogeneity*). These observations have been well characterized in Noonan syndrome and related disorders, and Alagille syndrome (see below). The most common genetic syndromes for which a specific disease gene has been defined are described below. Readers are also referred to GeneReviews.org, a collection of excellent peer-reviewed resources, which are updated periodically.

Alagille Syndrome (*JAG1* and *NOTCH2*)

Alagille syndrome was originally defined as the presence of bile duct paucity on liver biopsy in conjunction with three of the following five findings: cholestasis, CHDs, skeletal or ocular abnormalities, or typical facial features (217,218) (Fig. 26.6). An autosomal dominant disorder, it was noted that a subset of patients with clinical features of Alagille syndrome had deletions of chromosome 20p12 (219–221). The Notch ligand, *JAG1*, was subsequently mapped into the commonly deleted region (222). Two reports identified mutations of *JAG1* in patients with Alagille syndrome and therefore demonstrated that *JAG1* is a disease gene for this disorder (223,224). *JAG1* mutations were also identified in family members with milder presentations or microforms of Alagille syndrome, demonstrating that there is a broad spectrum of clinical phenotypes associated with *JAG1* mutations.

Figure 26.6. Alagille syndrome. Representative facial features of two boys with Alagille syndrome aged 7 months (A) and 9 years (B). Note the broad forehead, deep-set eyes, rounded tip and pear-like shape of the nose, and pointed chin. The features give the face an inverted triangle appearance. (Courtesy of the parents; David Piccoli, MD; and Elizabeth Goldmuntz, MD, The Children's Hospital of Philadelphia.)

Alagille syndrome is now recognized to be a genetically heterogeneous disorder. Approximately 5% of patients will have a chromosomal deletion involving one copy of the entire *JAG1* gene, whereas most will have various intragenic *JAG1* mutations (225,226). Using the most sensitive techniques, *JAG1* mutations can be identified in 94% of patients with features of Alagille syndrome (225,226). A minority of patients will have *NOTCH2* mutations (74). Mutations introducing a shift in the reading frame of the genetic code (so-called frameshift mutations) are the most common type of *JAG1* mutation, but missense mutations that alter only a single amino acid have also been identified. As a result of most *JAG1* deletions and mutations, there is presumably half the amount of functional protein. Therefore, the disease mechanism appears to be that of haploinsufficiency.

Alagille syndrome is characterized by right-sided CHDs including peripheral pulmonary stenosis (diffuse hypoplasia of the pulmonary arterial bed as well as discrete stenosis), pulmonary valve stenosis, and tetralogy of Fallot. Left-sided lesions and septal defects have also been reported (227). Examination of pedigrees of patients with Alagille syndrome and/or *JAG1* mutations suggested that some patients with CHDs without overt hepatic involvement would have *JAG1* mutations. Indeed, *JAG1* mutations have been identified in patients and kindred who do not have overt hepatic disease and therefore do not meet the classic criteria of Alagille syndrome but have CHDs typical of Alagille syndrome and other mild syndromic features (228,229). Therefore, the diagnosis of Alagille syndrome or *JAG1* mutation should be considered in families in which more than one member has a right-sided heart defect. Conversely, patients with right-sided CHDs should be carefully examined for subclinical features of Alagille syndrome and questioned for a relevant family history to identify the patient at risk for Alagille syndrome or a *JAG1* mutation. Patients suspected of having Alagille syndrome should undergo cytogenetic testing including a karyotype and analysis for deletion of chromosomal region 20p12. Testing for intragenic *JAG1* mutations is now clinically available.

Several studies have reported additional vascular anomalies and complications in patients with Alagille syndrome, highlighting the fact that the observed arteriopathy can affect more than the pulmonary arterial bed. In particular, Kamath et al. (230) reported that 9% of their cohort with Alagille syndrome had noncardiac vascular anomalies or events including basilar, internal carotid, and middle cerebral artery aneurysms. Other reported arterial anomalies include renal artery stenosis and moyamoya disease. Vascular events accounted for 34% of the mortality in this cohort. The true prevalence of such arterial anomalies is still unknown; thus, it is not yet clear whether routine screening for other vascular anomalies is clinically warranted. However, these observations point to a diffuse vasculopathy in Alagille syndrome and should heighten the clinician's awareness for these potentially devastating complications.

A small number of patients with clinical features of Alagille syndrome do not have *JAG1* mutations but have mutations in its ligand, *NOTCH2*. In particular, McDaniell et al. (74) identified two unrelated kindred with *NOTCH2* mutations out of 11 *JAG1* mutation-negative patients with the clinical features of Alagille syndrome. Of note, all of the patients with *NOTCH2* mutations had renal manifestations, which are less commonly seen in the cohort of Alagille patients with *JAG1* mutations. These results also further highlight the critical role of the *NOTCH* signaling pathway in cardiovascular development and disease.

Holt-Oram Syndrome (*TBX5*)

Holt-Oram syndrome is the most common “heart–hand” syndrome (upper limb and CHDs) and is estimated to occur in

1 of 100,000 live births. The skeletal anomalies of this autosomal dominant disorder involve the preaxial radial ray and are fully penetrant (i.e., everyone with the diagnosis of Holt-Oram syndrome must have a skeletal anomaly), although they range in severity (231,232). Subclinical changes may include only radiographic evidence of abnormal carpal bone, whereas others have obvious severe manifestations such as phocomelia. The thumb is frequently affected and can be triphalangeal, hypoplastic, or absent. Skeletal anomalies can be seen in one or both upper limbs and may be symmetric or asymmetric.

Approximately 75% of patients diagnosed with Holt-Oram syndrome have CHD (233). Although atrial and ventricular septal defects are most commonly seen (58% and 28%, respectively), additional CHDs including atrioventricular septal defects, conotruncal anomalies, and left-sided defects are also reported. Atrioventricular conduction delay, which can begin as first-degree atrioventricular block and progress to complete heart block, is also an important cardiovascular feature.

Linkage analyses performed on families demonstrating autosomal dominant inheritance identified a disease locus at 12q24 (234,235). Subsequent investigations identified mutations in *TBX5* in patients with Holt-Oram syndrome (236,237). Since the initial discovery, nonsense, frameshift, and missense mutations have been identified in familial and sporadic cases. Mutations of *TBX5* are found in approximately 70% of patients with the clinical features of Holt-Oram syndrome. Presumably those with the correct diagnosis of Holt-Oram syndrome in whom a mutation cannot be readily identified have a mutation in a regulatory domain that is not routinely tested since the disorder is not thought to be genetically heterogeneous. Although in most cases the diagnosis of Holt-Oram syndrome can be reliably made by clinical examination, genetic testing for *TBX5* mutations is clinically available in several specialized laboratories and may be useful in specific situations where the diagnosis is ambiguous or needed for prenatal counseling.

The diagnosis of Holt-Oram syndrome should be considered in the patient with heart and upper limb anomalies. Given the variable phenotype, Holt-Oram syndrome should also be considered in the patient with an apparently isolated septal defect and family history of septal or upper limb anomalies. The patient suspected of having Holt-Oram syndrome should be evaluated for radial ray and cardiac and conduction abnormalities. Although it is most commonly a sporadic rather than familial disorder, selected family members of affected members should be examined for subtle features to allow for appropriate genetic counseling. Some reports have suggested a genotype/phenotype correlation (i.e., certain mutations may be associated with more severe cardiac or skeletal manifestations), but caution must be exercised for the individual when counseling about the implications of each mutation.

Noonan Syndrome Spectrum (Noonan Syndrome, LEOPARD, Cardiofaciocutaneous Syndrome, Costello Syndrome)

Several phenotypically similar, but genetically distinct, multiple anomaly syndromes have been the subject of tremendous clinical and molecular genetic and cardiology research. They are often known collectively by the most common and familiar disorder in the group (“Noonan syndrome spectrum”) or by the Ras/mitogen-activated protein kinase (MAPK) biochemical pathway (“rasopathies”). Noonan syndrome, cardiofaciocutaneous (CFC) syndrome, and Costello syndrome are the result of mutations in the Ras/MAPK pathway (76) and have similar cardiac abnormalities, namely, CHDs, hypertrophic cardiomyopathy (HCM), and arrhythmia (86). Other clinical syndromes in this pathway, broadly defined, such as neurofibromatosis, type 1 and Legius syndrome, are not discussed.

Figure 26.7. Rasopathy syndromes: Noonan syndrome, CFC syndrome, Costello syndrome. A: On the left is a child with Noonan syndrome. B: In the middle is a 12-year-old girl with the CFC syndrome due to the most common *BRAF* mutation (exon 12) without any cardiac disease. C: The right lower panel shows a 16-year-old girl with Costello syndrome due to the typical *HRAS* G12S mutation. She has severe hypertrophy of the left ventricle (HCM) with mitral valve stenosis and sub-aortic obstruction (see [86], Table III, Supplemental patient 6) (Each photo was kindly provided by the family.)

Noonan syndrome occurs in 1 per 1,000 to 1 per 2,500 live births diagnosed clinically (98,238,239) (Fig. 26.7A). There is a characteristic facial appearance (ptosis, hypertelorism, low-set ears, low posterior hairline), webbed neck, pectus excavatum, bleeding diathesis, lymphatic issues, learning disabilities, variable intellectual disability, and cryptorchidism. Noonan syndrome is genetically heterogeneous with at least seven causative genes identified including *PTPN11*, *SOS1*, *KRAS*, *RAF1*, *NRAS*, *BRAF*, and *SHOC2* (98). Linkage analyses and candidate gene studies in patients with Noonan syndrome first identified mutations in the gene *PTPN11*, which encodes the non-receptor-type protein tyrosine phosphatase SHP-2 (src

homology region 2-domain phosphatase-2) that functions in the ras/MAPK pathway (99). Subsequent studies identified additional mutations in genes participating in the same molecular genetic pathway. Approximately half of patients with Noonan syndrome have a mutation in *PTPN11* (99,100,240–242). Genotype-phenotype analyses demonstrate that mutations in specific disease genes correlate with specific clinical features (76,98).

At least 80% of clinically defined Noonan syndrome patients have a cardiovascular abnormality, 60% of which are CHDs and 20% have HCM (98). Pulmonary valve stenosis, often with an atrial septal defect, is most common (25% to 35%) overall and most commonly associated with *PTPN11*

mutations. Additional CHDs include secundum-type atrial septal defect, ventricular septal defect, tetralogy of Fallot, pulmonary artery stenosis, coarctation of the aorta, incomplete atrioventricular septal defect (primum-type atrial septal defect), and polyvalvulopathy (98,101). HCM occurs in approximately 20% of patients with Noonan syndrome, especially those with a *RAF1* mutation and uncommonly with a *PTPN11* mutation. Patients with *KRAS* mutations have the most severe phenotype, and *SOS1* mutations result in a lower prevalence of cognitive delays. *SHOC2* is more likely to have mitral valve prolapse and septal defects, growth hormone deficiency, distinctive hyperactive behavior, hypernasal speech, and the distinctive easily pluckable hair.

Most cases of Noonan syndrome are sporadic, although families with a pattern of autosomal dominant inheritance are well known. There is marked clinical variability among affected individuals, and some parents have been diagnosed with this disorder only after the diagnosis of their more severely affected offspring.

Mutations of *PTPN11* have also been found in syndromes whose features overlap with those of Noonan syndrome, demonstrating that these are allelic disorders sharing a common genetic basis. Mutations of *PTPN11* have been identified in several patients with Noonan-like/multiple giant cell lesion syndrome, a syndrome characterized by features of Noonan syndrome and giant cell lesions of bone and soft tissue (cherubism) (100,102,243,244). A subset of patients with LEOPARD syndrome has also been found to have *PTPN11* mutations (93,245–247). LEOPARD syndrome is an autosomal dominant disorder characterized by multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary valve stenosis, HCM, growth retardation, abnormal genitalia, and sensorineural deafness. LEOPARD syndrome itself appears to be genetically heterogeneous since not all patients with this clinical diagnosis have a *PTPN11* mutation (93,246). Although *PTPN11* mutations resulting in Noonan syndrome are thought to confer a gain in function of the encoded protein, SHP-2 (99), mutations found in LEOPARD syndrome appear to have a dominant negative effect (248), which may explain the distinct phenotype. The ability to induce cardiomyocytes to pluripotent stem cells from a patient with LEOPARD syndrome heralds a new era of research for this group of syndromes (249). The researchers noted in vitro features of sarcomeric organization and preferential localization of *NEATC4* in the nucleus, which correlate with a potential hypertrophic state, thus providing an insight to the disease phenotype.

CFC syndrome and Costello syndrome are usually distinguishable from Noonan syndrome in the older child, but can be quite similar in the fetus, infant, and very young child (Fig. 26.7B,C). Whereas CFC syndrome can be caused by three genes (*BRAF*, *MEK1*, *MEK2*) (76,250), Costello syndrome is defined only by *HRAS* (76). As with Noonan syndrome, children with CFC syndrome also have relative macrocephaly, hypertelorism, and ptosis, but tend to have coarser facial features with sparse eyebrows and eyelashes, and dry skin (follicular hyperkeratosis). Costello syndrome also has coarse facial features, with ulnar deviation of the hand, curly (or very straight) hair, hyperpigmentation, loose skin, deep palmar and plantar creases, papillomata, and premature aging. Posterior fossa crowding can lead to Chiari 1 malformation, hydrocephalus, and syrinx (251). Developmental delays are always present, and intellectual disability is typically in the range of moderate mental retardation. Costello syndrome has a 10% to 15% risk of neoplasia, notably rhabdomyosarcoma.

The overall frequency (~80%) of any cardiovascular abnormality is nearly identical in CFC syndrome, Costello syndrome, and Noonan syndrome (86); HCM is more common (about 60%) in Costello and LEOPARD syndromes. Atrial

tachycardia, especially multifocal atrial tachycardia, is most common in Costello syndrome.

Kabuki Syndrome (*MLL2*)

In the previous edition of this textbook, Kabuki syndrome was listed as a syndrome with a “presumed, but unknown” cause. However, that is no longer the case. Affected patients have a characteristic expressionless facial appearance (reminiscent of the Japanese Kabuki theater actors) including elongated palpebral fissures with everted lower lids, arched eyebrows, sparse lateral brows, large pinnae, and fetal finger pads. Anomalies of the kidney and digits, immunologic and feeding problems, and intellectual disability are common. Because of tremendous phenotypic heterogeneity, the search for a causative gene was elusive until exome sequencing identified *MLL2* (which encodes a Trithorax-group histone methyltransferase) as the gene for Kabuki syndrome (89). Other researchers have described additional mutations and confirmed the original phenotype-genotype correlation that showed classic cases are most likely to be mutation-positive (90).

Atrial and ventricular septal defects are the most common CHDs in Kabuki syndrome. An increased frequency of left-sided CHDs, including HLHS and Shone’s like complexes had been reported in a clinical review (91), and also, in those with molecular confirmation (89,92). This will likely provide valuable information for ongoing candidate gene mapping for this group of CHDs.

CHARGE Syndrome (*CHD7*)

Whether the CHARGE malformation complex should be termed an association or syndrome (252) was resolved after the discovery of causative mutations in the chromodomain helicase DNA-binding gene (*CHD7*) on chromosome 8q12.1 (138). The cause of CHARGE syndrome is likely to be genetically heterogeneous given that *CHD7* mutations have been found in approximately 65% of patients diagnosed clinically (81,138,253–255). The original diagnostic criteria specified coloboma (usually involving the retina or choroid), CHDs, choanal atresia (membranous or bony), retardation of postnatal growth and development (including hypotonia), brain anomalies, genitourinary anomalies (more commonly recognized in males, including hypogonadotropic hypogonadism), and external ear anomalies (small, square, cupped pinnae) and/or deafness (conduction, sensorineural, mixed) (Fig. 26.8). The mnemonic was updated to highlight the diagnostic value of cranial nerve weakness or palsy (especially facial asymmetry) and hypoplasia of the cochlea and semicircular canals. Oral clefts and neurogenic swallowing problems are now appreciated as supportive of the CHARGE syndrome (253,256). The developmental, behavioral, and personality profile is complex since visual and auditory sensory handicaps exaggerate cognitive limitations and may include some features of autism (252).

CHDs have always been part of the core phenotype, and the availability of molecular testing provides more accurate analysis of a core phenotype. A CHD was present in 92% of *CHD7* mutation-positive and 71% *CHD7* mutation-negative individuals (81). Assorted CHDs have been reported, with conotruncal and aortic arch anomalies consistently overrepresented in clinical series. Features of the DiGeorge phenotype have been observed concurrently in patients with CHARGE syndrome (256). A detailed review of the molecular and phenotypic aspects of CHARGE syndrome found a similar occurrence of CHDs among those who were mutation positive and mutation negative; however, more sophisticated analysis was limited by the incomplete molecular typing (82).

The frequency of the CHARGE syndrome has been reported to range from 1 per 10,000 to 1 per 15,000 live births, although one population-based study estimated a frequency of

Figure 26.8. CHARGE syndrome. The characteristic ear anomalies include pinnae that are severely malformed (A), protruding (B), or small (C), as in this 5-year-old girl with very mild facial features and laryngotracheomalacia. She carries the *CHD7* mutation and had a more severely affected brother, presumably representing gonadal mosaicism. (Courtesy of the parents; Margaret A. Hefner, MS, CGS; and the CHARGE Syndrome Foundation, Inc.)

1 in 8,500 live births (257). Most cases of the CHARGE syndrome are sporadic in occurrence, but autosomal dominant inheritance and germline mosaicism, long clinically suspected, have now been confirmed by molecular testing (81).

Other Common Conditions

Table 26.4 lists syndromes that are presumed to be due to a mendelian gene based on observed family inheritance (e.g., affected siblings with Fryns syndrome suggest autosomal recessive inheritance). Also listed are familiar conditions that have more than one cause, such as heterotaxy, and those that are usually not associated with a single genetic cause such as vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities (VACTERL) association or hemifacial microsomia (HFM).

Heterotaxy

Heterotaxy is neither a typical genetic syndrome nor an isolated CHD, but a familiar malformation complex involving defects of right–left axis determination (reviewed by 129). The birth prevalence is approximately 1 in 10,000 (130). Heterotaxy implies that the laterality of thoracoabdominal viscera is neither situs solitus (normal position) nor situs inversus (mirror image). Cardiac, pulmonary, renal, gastrointestinal defects, and minor systemic venous anomalies such as interruption of the inferior vena cava (258) may also be accompanied by midline defects of the brain and face (131). Heterotaxy can, thus, be viewed as a developmental field defect or laterality sequence.

Family studies have been invaluable in delineating the genetic basis of heterotaxy. Kindred in which some members had situs inversus and others had heterotaxy, or when some individuals had isolated CHDs such as transposition of the great arteries or double-outlet right ventricle and others had overt heterotaxy syndrome, suggested that laterality defects represent a developmental spectrum. Recognized risk factors for heterotaxy include maternal insulin-dependent diabetes,

but assorted chromosome abnormalities have also been identified (22,130). The first genetic basis of a laterality disorder was observed in Kartagener syndrome in which situs inversus is accompanied by bronchiectasis, chronic sinusitis, nasal polyps, and infertility due to immotile sperm from impaired ciliary function. Autosomal recessive inheritance, and less commonly, autosomal dominant and X-linked recessive inheritance, have been described in Kartagener syndrome. Genetic heterogeneity is supported by the discovery of mutations in the gene encoding axonemal dynein intermediate chain on chromosome 9p21, with additional loci on 7p21 and 5p14 (259,260). The presence of CHD and heterotaxy in a study of primary ciliary dyskinesia confirmed that they are part of a spectrum, and connected by ciliary dysfunction (261).

Pedigrees with X-linked patterns of inheritance for heterotaxy led to the discovery of the first heterotaxy gene, *ZIC3*, which maps to Xq26.2 (262,263). Many genes have also been found in animal models to participate in the establishment of asymmetry and laterality in the embryo. Several of these genes were tested for mutations in patients with heterotaxy and are implicated as potential disease-related genes including *LEFTY A*, *CRYPTIC/CFC1*, *ACVR2 β* , *NKX2.5*, and *CRELD1* (129,264–269). However, such studies were limited and additional research is needed to define the contribution of these candidate genes to the disease spectrum.

VATER/VATERR/VACTERL Association

The VACTERL association is usually a sporadic occurrence of unknown cause. In rare cases as an association, it can occur in a child with an underlying syndrome, such as trisomy 18 (270) or trisomy 21 (132). The original acronym was VATER to include vertebral anomalies, anal atresia (with or without fistula), tracheoesophageal fistula, and renal dysplasia. Later, radial defects including radial or thumb absence or hypoplasia, and preaxial polydactyly expanded the R. The presence of CHDs, a single umbilical artery, and lower spine anomalies were also included. A general diagnostic guideline required three or more defects to establish the diagnosis (133).

Various types of CHDs have been reported in VACTERL association using traditional clinical series, epidemiologic analyses (133,271), and more recent cluster analysis (132). VACTERL is generally a sporadic occurrence. However, when VACTERL occurs with hydrocephalus (especially due to aqueductal stenosis) and/or is associated with a family history of hydrocephalus, it is viewed as a distinct mendelian disorder (272). Autosomal dominant, X-linked recessive, and autosomal recessive inheritance have been described. Because the VACTERL association is not thought to have a single pathogenetic pathway, it would not be suspected of having a single causative gene. When sonic hedgehog signaling is defective in mice, the pattern of defects resembles VACTERL (273), which may provide insights into the human condition.

Hemifacial Microsomia, Facioauriculovertebral Spectrum, and Oculoauriculovertebral Spectrum, Goldenhar Syndrome

Although Goldenhar syndrome is the most familiar eponym, it is perhaps the least accurate description of what is considered a spectrum of craniofacial anomalies (72). Referring to the complex as possible errors in morphogenesis of the first and second branchial arches is cumbersome though accurate. A practical approach using the acronym OMENS is favored by many plastic surgeons and builds on the fundamental HFM; the additional defects of eye, mandible, ear, nerve, and soft tissue involvement are added (274). Many dysmorphologists prefer the literal terms facioauriculovertebral spectrum and oculoauriculovertebral spectrum (OAVS). A few cases are familial, and autosomal dominant inheritance has been reported. Maternal diabetes is a familiar association (275). Other risk factors that have been studied include vasoactive medications and vascular events (276).

Involvement is usually unilateral with variable hypoplasia of facial structures (including bone, soft tissue, ears, eyes, or mouth). Ear tags or ear pits, epibulbar dermoids (characteristic of Goldenhar syndrome), and deafness are also typical. Oral clefts may involve the lip, palate, and corner of the mouth, creating macrostomia. There can be associated vertebral, radial, or rib defects, as well as renal anomalies and midline brain defects (especially agenesis of the corpus callosum, encephalocele, and lipoma). The breadth of associated anomalies has prompted many descriptions of overlapping complexes (277,278).

The largest single-center review noted CHDs in almost one-third of the 87 patients who were defined as having oculoauriculovertebral spectrum (128). The authors acknowledged the wide range of previously reported frequencies (5% to 58%) and attributed this to the selection bias (clinical series, population-based ascertainment) and the variability in case definition. They reported tetralogy of Fallot and ventricular septal defect in about two-thirds of those with a CHD, but many other CHDs were noted. The increased frequency of conotruncal CHDs has led many investigators to suspect a role for neural crest cell migration in producing the head and neck anomalies.

Genetics of Isolated Congenital Heart Defects: *NKX2.5*, *GATA4*, *NOTCH1*

Little is known about the genetic basis of isolated, nonsyndromic CHDs although they constitute the vast majority of clinical cases. The evaluation of kindred with multiple affected members has begun to identify specific disease genes for isolated CHDs in recent years. In particular, the transcription factors *NKX2.5* and *GATA4*, and the regulator of cell fate, *NOTCH1*, have been identified as disease genes for a small subset of patients with specific types of nonsyndromic CHDs. These findings and the remaining questions are described below.

NKX2.5

Schott et al. (279) identified four families whose affected members most commonly had atrial septal defects and atrioventricular conduction disorders. An informative parametric linkage analysis identified a disease locus on chromosome 5q. The gene, *NKX2.5*, mapped into this locus and was already known to participate in cardiovascular development from animal models. Mutations of *NKX2.5* specific to each family were found in the affected members and were not found in any normal control subjects. Each mutation was predicted to alter the encoded protein function, and most mutations disrupted the highly conserved DNA-binding domain. Subsequent reports identified *NKX2.5* mutations in other sporadic and familial cases with atrioventricular conduction abnormalities with or without atrial septal defects (280,281). These studies not only identified the first disease gene for isolated CHD but also made the surprising discovery that *NKX2.5* was critical to atrioventricular nodal development and function over time.

Multiple subsequent studies report additional *NKX2.5* mutations in familial cases with atrial septal defect and atrioventricular block, as well as sporadic cases with atrioventricular block in the absence of CHD. Studies also report missense mutations of *NKX2.5* in sporadic cases with a variety of CHD without atrioventricular block, including some with conotruncal or left-sided defects; the pathologic significance of such mutations remains to be demonstrated (282–284). These studies suggest that *NKX2.5* plays an important role in a range of CHDs and particularly in atrioventricular conduction.

Though investigations continue, it is clear that patients with atrial septal defects and atrioventricular conduction abnormalities are at risk for having a mutation of *NKX2.5*. It is also clear that those patients with *NKX2.5* mutations who present with first-degree atrioventricular block can progress to complete heart block over time and even sudden cardiac death if the conduction abnormality goes undiagnosed (282). These data suggest that patients with an atrial septal defect warrant assessment by ECG for atrioventricular prolongation. If first-degree atrioventricular block is diagnosed, then periodic evaluation for progression to higher grades of atrioventricular block is indicated, even after surgical repair. It is also important to obtain a detailed family history for signs and symptoms of complete heart block and at times, it may be appropriate to screen immediate family members (first-degree relatives) by ECG for subclinical atrioventricular conduction abnormalities to identify underlying familial disease. Likewise, the immediate family members of a patient with atrioventricular conduction abnormalities with or without other CHDs might warrant similar screening. Mutation studies of *NKX2.5* are now clinically available and help identify the subset of patients with an atrial septal defect at risk for progressive conduction abnormalities.

GATA4

Garg et al. (285) first reported mutations in the transcription factor, *GATA4*, in two kindreds with septal defects: members of the first kindred had atrial septal defects, but members of the second kindred displayed a more heterogeneous phenotype with atrial septal defects, ventricular septal defects, and pulmonary valve stenosis. These findings were of particular interest given that *GATA4*, which maps to chromosome 8p22–p23.1, is a molecular partner with *NKX2.5* and is deleted in some patients with CHDs and chromosome 8p23 deletions. Subsequent investigators have reported *GATA4* mutations in familial cases of septal defects (280,281), and less commonly in sporadic cases with septal defects or other conotruncal defects (280,281,286–288). These findings, in conjunction with those

on *NKX2.5*, highlight the significance of this molecular pathway in cardiovascular development and disease.

NOTCH1

Studies of kindred with multiple affected members continue to identify novel molecular developmental pathways that contribute to cardiovascular disease and development. Most recently, Garg et al. (289) identified mutations in *NOTCH1* in two small families with bicuspid aortic valve and aortic valve stenosis. Of particular interest was that some patients did not have congenital bicuspid aortic valves but developed aortic valve calcification in later decades of life. Experiments confirmed that *NOTCH1* was expressed in the developing aortic valve. Experiments also suggested that *NOTCH1* mutations play a role in aortic valve calcification. Subsequent studies of small patient cohorts report rare *NOTCH1* mutations in sporadic cases with a range of left-sided cardiac defects, including aortic valve stenosis, bicuspid aortic valve, coarctation of the aorta, and HLHS (290–292). Though more work remains to be done to define the affected cohort, these studies highlight the important role of the NOTCH pathway in CHD.

GENETICS OF SPECIFIC CARDIAC LESIONS

The growing body of genetic information now allows the clinician to consider whether a patient with a specific type of CHD has an associated genetic alteration (Table 26.5). The clinician needs to consider whether additional genetic consultation or genetic testing is warranted. For example, mutations in *NKX2.5*, *GATA4*, *MYH6*, and *TBX5* have been identified in patients with atrial septal defects (237,279,285,293). Therefore, one can now consider whether a patient with an atrial septal defect has an associated syndrome (such as Holt-Oram syndrome) or mutation in one of these genes. Clinical testing for mutations in these genes is now available, allowing for improved diagnostics, family screening and genetic counseling, and risk assessment for associated features. Similarly, patients with tetralogy of Fallot may be either syndromic or nonsyndromic and are at risk for different genetic alterations accordingly (14) (Tables 26.1 and 26.5). A patient with tetralogy of Fallot should be carefully evaluated for features of one of the known associated syndromes including trisomy 21, 22q11.2 deletions, and *JAG1* mutations. The family history should be carefully reviewed for CHDs or associated syndromic features that might suggest a 22q11.2 deletion or *JAG1* mutation, for example. Table 26.5 lists known genetic alterations associated with specific CHDs to help the clinician move from the cardiac to a concurrent genetic diagnosis. Since all of these CHDs are genetically heterogeneous, this table can list only the currently known associated disease genes. As new diagnostic tests and clinical discoveries are made, this list is likely to become more extensive and clinically relevant. Of course, many other genetic syndromes associated with each CHD are known; only those with recognized specific genetic alterations are listed here.

GENETIC EVALUATION AND COUNSELING

Although most of the care for a patient with CHD focuses on the diagnosis and treatment of the heart itself, it is critical for the referring primary care provider and the cardiologist to consider whether genetic consultation and counseling is warranted both at the time of diagnosis of the CHD and in later years (139). The chances of finding additional congenital anomalies or syndromic features in a patient with a CHD are

high. Approximately 20% to 25% of infants ≤ 1 year of age have a noncardiac malformation, and approximately 5% to 17% have a genetic syndrome (11,22,294–299). The diagnosis of a genetic syndrome is more likely when growth and developmental delay are also present. Therefore, clinicians must examine the patient with a CHD with a critical eye for dysmorphic features, changes in body habitus, other congenital anomalies, neurocognitive deficits, or a family history of these same findings. It is increasingly evident that one should not ascribe neurocognitive deficits to surgery alone and must consider whether they are a symptom of an underlying genetic alteration instead. Even in the apparent absence of dysmorphic features or other congenital anomalies, patients with certain CHDs should be suspect for genetic syndromes based on the known frequency of such associations. For example, the patient with interrupted aortic arch type B is so commonly found to have a 22q11.2 deletion that referral for genetic consultation and testing should be considered even in the absence of overt dysmorphic features. Finally, given the highly variable and often subtle presentation of many genetic syndromes, a concurrent genetic diagnosis can be easily overlooked or delayed if a high level of suspicion and willingness to seek genetic consultation is not maintained.

Importance of Identifying a Genetic Syndrome or Genomic Imbalance

Identifying the underlying genetic syndrome or alteration in a patient with a CHD is of growing clinical importance. First, diagnosing the patient with a genetic syndrome allows for the early identification and treatment of associated *noncardiac* features. For example, the patient found to carry a 22q11.2 deletion can be evaluated and treated for commonly associated noncardiac features such as feeding disorders, palate anomalies, speech disturbances, hypocalcemia, and others. Knowing that a patient with a CHD has a 22q11.2 deletion may help define the cause of feeding disorders and failure to thrive, which might otherwise be accredited to heart failure alone. Second, establishing a specific genetic cause allows for appropriate family counseling regarding risks of recurrence (297). For example, parents of a patient with Alagille syndrome should be tested to determine if one of the parents is a carrier of a *JAG1* mutation since the parent with only subtle syndromic manifestations carrying the mutation has a 50% chance of having a second affected child. Depending on the age of the individual and circumstances, the geneticist may provide information about prenatal diagnosis including options for imaging the fetal heart and obtaining appropriate genetic tests. Third, establishing a genetic diagnosis in the future will most likely allow more accurate counseling regarding cardiac and noncardiac clinical outcome. Several studies already suggest that specific genetic syndromes are associated with a worse clinical cardiac prognosis (1–4). Finally, for many patients and their families, knowing whether a CHD is associated with an identifiable cause such as a chromosome abnormality, gene mutation, or genetic risk factor can be important. Ultimately, determining the patient genetic phenotype is essential to provide more accurate clinical care, estimation of prognosis, and assessment of risk (Table I in (295)). In the future, genotype may influence management strategy.

When to Refer the Cardiac Patient for a Genetics Evaluation

The increasing number of possible genetic diagnoses and the rapid development of new genetic tests necessitate a close collaboration between the referring primary physician,

TABLE 26.5

Disease Loci or Genes Associated with Specific CHDs Known to Date

Congenital Heart Defect	Associated Genetic Loci or Disease Genes^a
Atrial septal defect (with or without atrioventricular conduction blockade)	<i>TBX5</i> (Holt-Oram syndrome) <i>NKX2.5</i>
Atrial septal defect (without atrioventricular conduction blockade)	<i>GATA4</i> <i>MYH6</i>
Perimembranous ventricular septal defect	<i>TBX5</i> (Holt-Oram syndrome) <i>GATA4</i> 22q11.2 deletion Many syndromes including trisomy 21
Tetralogy of Fallot	<i>NKX2.5</i> <i>JAG1</i> (Alagille syndrome) <i>PTPN11</i> (Noonan syndrome) 22q11.2 deletion Many syndromes including trisomy 21
Truncus arteriosus	22q11.2 deletion
Interrupted aortic arch	22q11.2 deletion
Patent ductus arteriosus	<i>TFAP2β</i> (Char syndrome)
Atrioventricular septal defect	<i>CRELD1</i> 1p 8p23 Trisomy 21 (21q22)
Heterotaxy syndrome	<i>ZIC3</i> <i>CFC1</i> <i>ACVR2B</i> <i>Lefty2</i>
Valvar pulmonary stenosis	<i>JAG1</i> (Alagille syndrome) <i>PTPN11</i> <i>KRAS</i> <i>SOS1</i> (Noonan syndrome) <i>HRAS</i> (Costello syndrome) <i>BRAF</i> , <i>MEK1/2</i> (CFC syndrome)
Supravalvar aortic stenosis	<i>ELN</i>
Aortic valve stenosis/Bicuspid aortic valve	<i>NOTCH1</i>

cardiologist, and clinical geneticist (139). Much depends on the cardiologist's diagnostic ability, interest, and time to determine if a CHD is isolated, part of a familial CHD syndrome, or associated with other defects of a known syndrome or as of yet uncharacterized complex (153). Consultation from a clinical geneticist should be sought for the cardiac patient with the following: dysmorphic features, multiple congenital anomalies, neurocognitive deficits, or a family history of CHD, congenital anomalies, or neurocognitive deficits. Although, historically, learning disabilities or developmental delay have often been attributed to the cardiac defect and surgical intervention, these observations may instead prove to be independent problems that may indicate the presence of a genetic syndrome or chromosomal alteration. Families may also benefit from a genetic consultation for counseling purposes, particularly with respect to risks of recurrence. Early referral to a clinical geneticist allows the early diagnosis of associated noncardiac features, as well as early intervention and timely counseling. Finally, sometimes the primary care taker or cardiologist orders the basic genetic tests to screen for abnormalities with the intention

of consulting genetics if an abnormality is discovered. However, this practice may greatly underserve the patient with no detectable chromosomal alteration who nonetheless may have a genetic syndrome or the patient who could benefit from more specialized genetic testing. In addition, the number of clinically available genetic tests has increased remarkably in the last five years, ranging from single-gene mutation studies to genome-wide scans. As such genetic testing has become increasingly complex and requires the ordering physician to be ever more knowledgeable. Thus, genetic consultation should be considered in the suspicious patient to allow for specialized assessment and direction of genetic testing.

The Genetic Evaluation

The goal of the genetic evaluation is to establish a diagnosis and provide information to the patient and family about recurrence risk and expected outcomes that are known (297). The evaluation therefore considers both the patient under

evaluation and the family medical history in detail. Geneticists will first consider the specific type of CHD and associated congenital anomalies present in the patient. The geneticist (or genetic counselor) then obtains a complete family history of malformations and genetic conditions, including malformation syndromes (297). Information is also sought about recurrent miscarriages, sudden death in childhood, developmental delay, and mental retardation.

The geneticist's physical exam begins with an overall appraisal of habitus, facial appearance, and movements. Occasionally when an immediate general impression based on characteristic dysmorphic features provides rapid diagnosis, restraint and confirmation is needed. In addition to height, weight, and head circumference, measurements may be made of facial landmarks and distances, or other body parts to quantify the qualitative sense of hypertelorism, small pinnae, or long fingers. Most geneticists do not perform complete neurodevelopmental examinations, substituting modified office screening tests, reports from family members, previous formal testing, or functional appraisal of the individual's interactions and performance in the office setting.

Depending on whether the consultation is performed during an admission to the hospital or as an outpatient visit, emergently or as a scheduled visit, and whether the location is the tertiary care center or a small satellite clinic, diagnostic testing can be performed at the same time as the initial evaluation or requested to be obtained under the direction of the primary care giver and/or cardiologist. Radiographic and ultrasonographic tests may be ordered to define internal organ structure and function. Medical, educational, and therapeutic specialists may be requested to characterize multisystem involvement and to begin treatment.

Genetic Testing

Historically, the most commonly requested genetics test was a cytogenetic examination ordered as a karyotype of lymphocytes in fresh whole blood. A FISH analysis became complementary to a standard chromosome analysis, which was useful for rapid diagnosis (e.g., amniocentesis diagnosis of trisomy) and the detection of small deletions. Microarray technologies offer the most recent technique for detecting an alteration of DNA quantity and have become the test of choice to detect chromosomal deletions and duplications (137), although a standard karyotype is still necessary to detect mosaicism and chromosomal translocation. More rapid techniques to detect single nucleotide mutation in a panel of genes are also now available.

When a mendelian gene disorder is suspected, geneticists determine if molecular testing is available and whether the testing is being done at a research or clinical lab. Details are sought from the referral laboratory and literature. Before testing can be done, the genetics team needs to know if the laboratory is approved to report clinical results, how specimens are shipped, the cost and potential for reimbursement by insurance, the length of time it takes to complete the test, and how results are communicated. This process can consume as much time as the genetics examination itself.

Practically speaking, the timing and location of having these tests completed may be determined more by medical insurance coverage and less by referring physician or patient preference. Likewise, whether the individual will be permitted to return for a follow-up genetics visit is highly dependent on health care coverage. Regardless of whether the genetics evaluation was conducted on a critically ill neonate on an emergent basis, or during an extensive consultation with the extended family of multiply affected individuals, communication and collaboration with the cardiologist are essential. Of course,

the primary care physician and the individual (and family) should be included in all discussions.

A Partnership

Since approximately 75% of CHDs currently have no identifiable cause (11,22,154,294,296,298,299) or underlying condition, the notion of a formal genetic evaluation may appear to be unnecessary in many cases. However, the list of genetic causes of CHDs is expanding rapidly and is ever more difficult to understand, and many syndromes are now recognized to present with subtle and often unrecognized features. Moreover, options for clinical genetic testing are rapidly evolving and increasingly complicated. As the list of genetic causes and tests for CHDs continues to expand in length and complexity, and the list of genetic syndromes associated with CHDs grows as well, there is clearly a need for clinical partnership between primary caretakers, cardiologists, and geneticists. In many cases, the primary care taker and cardiologist will call on the geneticist for consultation as described in the previous sections. For example, when coarctation is confirmed in a young girl who is noted subsequently to have short stature, redundant neck skin, and low-set ears, the geneticist can confirm the suspected diagnosis of Turner syndrome and provide long-term counseling to the patient and family. In other cases, the geneticist may call upon the cardiologist to define the associated CHD in a patient under consideration for a particular genetic syndrome to assist with the diagnosis. For example, a geneticist may consider the diagnosis of Holt-Oram syndrome in a three-generation family with absent and unusual thumbs. Although *TBX5* mutation studies would be confirmatory, speedier diagnostic support would be provided by two-dimensional echocardiographic detection of a secundum atrial septal defect in mother and son.

It can be difficult to coordinate the cardiology and genetics consultations (295). Instead of being evaluated at different times, some patients are seen in cardiovascular genetics clinics with genetics and cardiology specialists working in tandem. With the assistance of supplemental imaging of other organs; confirmatory cytogenetic, molecular, or metabolic blood tests; and the proven test of time, clinicians may make a unifying diagnosis to enhance each case.

CONCLUSIONS

In concert with the field of human genetics, our understanding of the genetic contribution to CHDs has advanced dramatically over the last 10 years. The field has moved from detailing genetic syndromes to the definition of specific genetic alterations causing those clinical phenotypes. Specific genetic causes of isolated CHDs have also begun to be identified. The remarkable and rapid advancements in human genetics and developmental biology are likely to lead to new discoveries in the field of cardiovascular genetics in the near future. Given these discoveries, an increasing number of patients with a CHD could be given a concurrent genetic diagnosis. It will be of increasing importance for the cardiologist caring for patients with CHDs to have a working knowledge of these discoveries and available genetic testing. It will also be increasingly important for the general pediatrician and cardiologist to work in concert with the clinical geneticists and genetic counselors to identify concurrent genetic diagnoses. The clinical implications of the associated genetic diagnosis, such as associated noncardiac features, will be increasingly important to recognize and address. Already, genotype-specific management strategies have been developed in many fields and will

inform that of pediatric cardiology in the near future. The association between genotype and clinical outcome is also well established (1–4) and will play an increasingly important role in counseling. Most important, understanding the genetic basis of these disorders, in conjunction with advances in developmental biology, will improve our understanding of cardiovascular development and disease and allow for novel, improved management strategies (300).

Fetal Echocardiography and Fetal Cardiology

Charles S. Kleinman ■ Julie S. Glickstein ■ Ganga Krishnamurthy ■ Jodie K. Votava-Smith

HISTORICAL PERSPECTIVE

In the introduction to his epochal 1974 monograph, "Congenital Diseases of the Heart," Dr. Abraham M. Rudolph (1) emphasized the importance that characterization of the cardiovascular adaptation of the fetus during the months leading to delivery and the postnatal transition of the systemic and pulmonary circulatory system have in improving understanding of the clinical condition of the neonate, and in contributing to the formulation of logical and physiologically based management strategies for various forms of congenital heart disease. Toward this end, Rudolph and Heymann (2) developed techniques for the study of cardiovascular development, using chronically instrumented fetal lambs. Their studies included normal fetal animals, as well as fetuses in which pulmonary artery or ascending aortic banding was used to simulate pulmonary or aortic stenosis (PS or AS). Regional flow within the cardiovascular system was investigated through the use of radionuclide-labeled microspheres (3,4). These observations were extended to include the varied components of the transitional circulation, providing insights into the relative roles played by oxygenation, cord clamping, and the intrinsic fetal shunt pathways in the redistribution of blood flow in the fetus at the time of birth (5–8).

Rudolph's studies of the fetal lamb were postulated as a model for understanding the human fetal and transitional circulation, despite the recognition that the fetal lamb differed in substantial ways from the human fetus. These differences would be reflected in altered regional flow distribution to organs such as the brain, which constitutes a larger fraction of body mass in the primate and human than in the ovine fetus. In addition, the relative difference in the degree of "maturation" of the ovine neonate, compared with the human neonate, could also result in alterations in regional blood flow distribution between the two species.

In 1977, Rudolph's observations of the fetal lamb served as the foundation on which our understanding of the fetal and transitional circulation of the human fetus was based. In 1976, Dr. Frederick Morin completed a doctoral thesis toward his M.D. degree at the Yale University School of Medicine that was, in turn, based on the observations of a 1972 study (9) describing the use of M-mode echocardiographic recordings of fetal cardiac activity in the human fetus. This paper had speculated that fetal cardiac function in normal and abnormal

pregnancies could be analyzed through the use of the measurement of left ventricular ejection fraction from M-mode recordings of cardiac wall motion against time. The same publication predicted that the small size, complex anatomy, and rapid heartbeat of the human fetus would not allow complex congenital cardiac malformations to be diagnosed prenatally.

This served as the intellectual underpinning for the initiation of a clinical research project at the Yale University School of Medicine aimed at applying fetal echocardiography to validate in the human fetus the observations that had been documented in the ovine fetal model. The first findings of significance related to paradoxical motion of the interventricular septum, reminiscent of the findings postnatally in patients with cardiac malformations associated with volume- and pressure-overloaded right ventricles. M-mode echocardiography in the human fetal heart thus provided noninvasive confirmation that the findings that had previously been made in the ovine fetus, where the fetal right ventricle functions as the dominant ventricle, ejecting a larger stroke volume than the left ventricle at systemic blood pressure, held, as well, for the fetal human.

Subsequent studies were undertaken to characterize the development of the human fetal cardiovascular system and were presented at the annual meetings of the Society for Gynecologic Investigation and the Society for Pediatric Research in the spring of 1978. At the latter, Dr. Helen Taussig commented on the importance of these findings, which offered the potential for the diagnosis of congenital heart disease in early gestation, and the potential for termination of such pregnancies, to decrease the individual and societal burden of congenital heart disease in these children.

Thereafter, our attention was turned toward establishing a clinical role for fetal echocardiography. Although we had speculated in 1978 that such studies could be useful for the diagnosis of congenital heart disease, it was not until a year had passed that we were able to prove this. Our first peer-reviewed publication on this topic appeared in 1980 (10). This paper suggested indications for detailed fetal echocardiographic study in pregnancies deemed to be at high risk for congenital heart disease. M-mode and two-dimensional (2-D) echocardiography was used to document atrioventricular septal defect (AVSD) in a patient with left atrial isomerism and complete atrioventricular (AV) block, atrial flutter (AF), and hydrops fetalis. M-mode echocardiography was used to document tricuspid atresia and hypoplastic right ventricle in a second fetus. M-mode echocardiography was used to demonstrate the presence of complete heart block in the fetus of a mother with systemic lupus erythematosus.

This article was reviewed by Dr. Alexander Nadas in the 1981 edition of the Yearbook of Pediatrics (10). Dr. Nadas noted the potential for the use of the technique for research purposes, but he doubted the potential for a clinical role for fetal echocardiography, owing to the improbability of establishing such diagnoses before the legal limits for termination of pregnancy.

During 1980, publications from San Diego (11) and from London (12,13) documented the potential for examination of the fetal heart using sequential, segmental analysis of cardiac

Dr. Kleinman died just after submission of this chapter. His pioneering efforts in fetal echocardiography and physiology have set the stage for perinatal cardiology and innovations in care to the fetus that would not have been possible without his foresight. Charlie was brilliant, always a gentleman, had a fantastic sense of humor, and maintained gentle humility and courage to his last day. 'The professor' will be missed. He was a true friend.

HDA

structure. In 1981, deGeeter et al. from Strasbourg, hosted the first international meeting devoted to fetal echocardiography and clinical fetal cardiology.

In 1984, at the World Congress of Pediatric Cardiology, Fermont et al. (13) from Paris, reported their experience with four-chamber screening of the fetal heart for the detection of congenital heart disease. This was followed by the description provided by Allan et al. (14) of a regional screening program in London. She went on to train ultrasonographers throughout Great Britain and the Continent to participate in similar screening programs throughout Europe.

Anatomic

Increased nuchal fold thickness

Fetal cardiac arrhythmia

Irregular rhythm

Tachycardia (>180 bpm) in absence of amnionitis

Fixed bradycardia

Nonimmune hydrops fetalis

Abnormal fetal situs

Suspected fetal heart malformation on screening ultrasound

Lack of reassuring four-chamber view during basic obstetric scan

bpm, beats per minute.

INDICATIONS FOR FETAL ECHOCARDIOGRAPHY

While it must be recognized that most cases of congenital heart disease result from pregnancies in women who are not identified in advance to be at higher-than-average risk for congenital heart disease, most women referred for detailed fetal echocardiographic study have been judged to be at risk according to factors defined as fetal, maternal, or familial risks (Table 27.1).

SCREENING FOR CONGENITAL HEART DISEASE

As noted above, most infants with congenital heart disease are born to women without high-risk indications for congenital heart disease. Fermont et al. (13) documented that the identification of fetuses with abnormal four-chamber views of the heart would improve case findings of major forms of congenital heart disease. The normal four-chamber view of the fetal heart may be obtained in approximately 95% of fetuses examined between the late second and early third trimesters of pregnancy. The fetal heart is normally a midline structure, with the apex pointing leftward toward the fetal stomach. The heart lies in a horizontal orientation, above the transverse liver. By orienting the ultrasound transducer approximately 30 degrees cephalad from the transverse plane where the fetal abdominal circumference is measured, a tomographic view of the fetal heart is obtained (Fig. 27.1) that demonstrates the four-chamber anatomy of the fetal heart. The central fibrous body of the normal fetal heart is intact, with the septal leaflet of the tricuspid valve inserting slightly closer to the cardiac apex than the insertion of the anterior leaflet of the mitral valve. The atrial cavities and the interposed atrial septum are visualized, with the foramen ovale representing the major source of blood flow into the left atrium from the inferior vena cava (IVC). The atrial septum primum undulates in the left atrial flow stream from the IVC and functions as a flap valve that functionally seals

Figure 27.1. Normal four-chamber view of the fetal heart during midtrimester. Note the relatively equal transverse diameters of the right and left atria (RA, LA) and the right and left ventricles (RV, LV). The septal leaflet of the tricuspid valve is inserted into the central fibrous body of the heart in a position that is slightly offset toward the apex of the heart in comparison with the site of insertion of the anterior mitral leaflet to the central fibrous body. The moderator band is seen at the apex of the right ventricle. The posterior inflow portion of the ventricular septum is interposed between the two ventricular chambers. The foramen ovale represents an unrestricted flow orifice between the IVC and the left atrium. Relatively highly oxygenated umbilical venous return from the IVC is preferentially shunted into the left atrium through the left ventricle and into the descending aortic distribution. This provides the most highly oxygenated arterial blood to the fetal coronary arterial and cerebral circulation.

the foramen ovale following birth, owing to increased pulmonary venous return consequent to gaseous expansion of the lungs and postnatal decrease in pulmonary vascular resistance. The atrial chambers are normally symmetrical in appearance as are the ventricular chambers. The right ventricular chamber appears slightly foreshortened owing to the moderator band at the ventricular apex. The right ventricular surface of the ventricular septum is more coarsely trabeculated than the left ventricular septal surface. In the short-axis view, the two papillary muscles of the mitral valve are seen, and neither of these muscles is associated with the ventricular septum, whereas the tricuspid valve characteristically has a chordal insertion to the conal region of the right ventricular outflow tract.

Abnormalities of four-chamber anatomy may characterize certain forms of congenital heart disease. In many cases, the

primary structural abnormality of the heart may be apparent in the view of the central fibrous body. Such defects may include complete atrioventricular septal (canal) defect, hypoplastic left heart syndrome (HLHS), hypoplastic right heart syndrome, Ebstein malformation of the tricuspid valve, and various forms of single ventricle (Fig. 27.2). Disproportion of atrial or ventricular chambers may reflect altered flow patterns through the fetal cardiovascular system (15). In such cases, the four chambers of the heart may change their volume and or wall thickness to reflect the volume and pressure of blood flow through them. Pulmonary valve (PV) stenosis, for example, may be associated with right ventricular wall hypertrophy, with decreased chamber volume secondary to increased right-to-left shunting across the foramen ovale, with right ventricular hypertrophy or with increased chamber

(See legend, following page)

volume if tricuspid regurgitation occurs (16). Similarly, disproportionate development of atria and ventricles may occur in the presence of discrete obstruction to left ventricular outflow (Fig. 27.3) (17–19). The latter findings have served as the foundation for the development of the first programs for fetal intervention.

The sensitivity and specificity of abnormal four-chamber screening for congenital heart disease has been discussed repeatedly in the literature during the past decade, with claims varying from a sensitivity of 0% to 10% (e.g., the RADIUS trial in the United States) (20–22) to a sensitivity of >80%, with most series suggesting a sensitivity in the range of approximately 40% (10,23–49) (Table 27.2).

Based on claims of the utility of four-chamber screening for congenital heart disease, bodies such as the American College of Radiology, the American College of Obstetrics and Gynecology, and the American Institute of Ultrasound in Medicine have recommended that four-chamber screening views of the heart be included in the evaluation of all fetuses undergoing ultrasound examination, regardless of indication.

Views of the ventricular outflow tracts may demonstrate ventriculoarterial connections and allow the integrity of the ventricular septum to be evaluated. The right ventricular outflow through the main pulmonary artery typically proceeds in a posterior sweep to the ductus arteriosus, the descending thoracic aorta, and the pulmonary arterial bifurcation, with the left pulmonary artery continuing posteriorly and the right pulmonary artery arising at a right angle where it passes under the aortic arch. The left ventricular outflow tract (LVOT) continues into the ascending aorta, which ascends vertically toward the head. The ascending aorta and main pulmonary artery crisscross one another after emerging from their respective outflow tracts. Tomographic imaging demonstrates the perpendicular courses of these great arteries by showing one vessel in a longitudinal view while the second vessel is seen as a circular cross section (Fig. 27.4). The presence of subvalvar, valvar, and/or supravulvar obstruction can be detected, and outflow tract abnormalities such as ventricular septal defect (VSD), conal septal malalignment, double-outlet ventricle, or arterial transposition may be documented (Fig. 27.5).

The sensitivity and specificity that are added to four-chamber screening of the fetal heart by the inclusion of long-axis views of the outflow tracts have resulted in revised standards for screening echocardiography by the American College of Radiology, the American College of Obstetrics and Gynecology, and the American Institute of Ultrasound in Medicine.

ECHOCARDIOGRAPHIC ASSESSMENT OF FETAL CARDIOVASCULAR PERFORMANCE

M-mode echocardiographic studies of the human fetus provide insight into the relative size and pressure of the fetal ventricles. The timing of mechanical events during various phases of the cardiac cycle as reflected by wall motion, and motion of the cardiac valves may be used to analyze cardiac rhythm (10) (Fig. 27.6).

Two-dimensional imaging may provide insight into relative chamber and blood vessel volume and pressure. The addition of color flow Doppler adds further information concerning the function of the AV and semilunar valves and flow within important fetal flow pathways such as the ductus venosus (DV), foramen ovale, and ductus arteriosus (Fig. 27.7).

Feit et al. (50) used 2-D imaging of the fetal foramen ovale to estimate interatrial volume flow and demonstrated that fetuses with left heart obstruction had smaller transatrial flow volumes, whereas patients with right heart obstructive lesions had larger-volume right-to-left interatrial shunts. Berning et al. (51) emphasized the importance of color flow in determining flow volume and direction across the fetal ductus arteriosus and foramen ovale in the diagnosis of left heart hypoplasia and/or obstruction to right ventricular outflow (Fig. 27.8).

Pulsed Doppler flow analysis has been used to estimate regional blood flow distribution within the human fetus during the third trimester of pregnancy. The radionuclide-labeled microsphere studies of Heymann and Rudolph (2) had demonstrated that in the third trimester fetal lamb, the fetal right ventricle ejects 67% of the combined output of the two ventricles, with only approximately 8% of the combined output traversing the high-resistance pulmonary vascular bed. This 8% of combined output enters the fetal left atrium as pulmonary venous return and combines with relatively oxygen-rich pulmonary venous return streaming through the DV and IVC, amounting to approximately 25% of combined ventricular output. Thus, 33% of combined ventricular output crosses the mitral valve and is ejected as left ventricular output. This relatively oxygen-rich blood is preferentially distributed to the coronary arteries and cerebral circulation. In the 1970s, Dr. Rudolph had estimated that the relatively larger brain in the primate and human would probably demand a larger volume of left ventricular output during fetal life. He estimated that the ratio of right-to-left ventricular combined output in the human would be in the range of 55%/45%. Doppler flow studies in the human fetus have confirmed that estimate (52,53).

Friedman et al. (54–56) described studies on isolated strips of myocardium as well as on whole heart preparations

Figure 27.2. Montage of 6 four-chamber views of the fetal heart (A–F). Five cases of congenital heart disease (A–E) involving the central fibrous body of the heart are contrasted with a normal four-chamber view (C). **A:** Four-chamber view of the heart of a fetus with tricuspid atresia and ventricular disproportion favoring a large left ventricle (LV). There is an absent right AV connection, with a solid bar of muscle interposed between the right atrium (RA) and the right ventricle (RV). The sole inflow to the right ventricle is through a small muscular VSD, and the right ventricular cavity is hypoplastic. There is a large, single, mitral AV valve and a large left ventricle. **B:** Marked ventricular disproportion favoring the right ventricle in a patient with hypoplastic left heart. The left atrium (LA) is small and thick walled. The mitral valve is miniscule, and the left ventricle is hypoplastic, with a hypertrophic, fibroelastotic left ventricle. **C:** Normal four-chamber view of the fetal heart with proportionate ventricular and atrial cavities, normal AV valves, and intact central fibrous body. **D:** Unbalanced, right ventricular not dominant, AVSD in a fetus with trisomy 21. Although not visualized in this view, this fetus also had a hypoplastic aortic arch. **E:** Atrial and ventricular disproportion, with enlarged right-sided cardiac chambers in a fetus with the Ebstein malformation of the tricuspid valve. The tricuspid valve leaflets are redundant and thickened, with inferior displacement of the septal (visualized) and posterior (not seen in this view) leaflets. The anterior leaflet (visualized) is redundant and sail-like. A significant portion of the inflow tract of the right ventricle is “atrialized” owing to the apical displacement of the tricuspid valve. **F:** A balanced, complete, AVSD in a hydropic fetus with trisomy 21. The central fibrous portion of the heart is deficient, with a large ostium primum atrial septal defect (ASD), inflow VSD, and a common AV valve.

from mature and fetal sheep. These studies demonstrated that mature myocardium generates higher tension (pressure) at any end-diastolic length (volume) than does fetal myocardium. In addition, passive tension (pressure) is higher at any level of diastolic length (volume). These myocardial properties explain the findings of fetal animal studies, suggesting limited afterload and preload reserve. Possible explanations for the intrinsic differences between fetal and mature myocardium have been offered, including a paucity of contractile elements within immature myocytes, the increased amount of nuclear material within mature myocytes, the relatively haphazard orientation of contractile elements within immature myocardium versus the parallel orientation of the contractile elements of mature myocardium, and the relative deficiency of sarcomeres in fetal myocardium versus the rich distribution of sarcomeres and t-tubules that provide intracellular calcium stores to the contractile elements of mature myocardium.

Pulsed Doppler and Doppler tissue imaging studies of biventricular diastolic filling are suggestive of restrictive ventricular diastolic physiology throughout mid and late gestation (57–60) (Fig. 27.9). Recently, normative data have been presented for strain and strain rate analysis of the fetal myocardium (61,62). It is unclear at this point whether this technique will offer a reliable and reproducible means of analyzing fetal systolic and diastolic performance.

Rudolph (1) has summarized the known characteristics of fetal myocardium and the in utero environment to explain the proclivity of fetuses toward the development of interstitial edema and hydrops fetalis (Fig. 27.10). These findings explain the frequent development of hydrops fetalis among fetuses with pressure or volume overload, or sustained bradyarrhythmias or tachyarrhythmias.

Huhta et al. (63,64) have proposed the use of a Cardiovascular Profile Score to determine the overall status of

Figure 27.3. Montage of five four-chamber views of the fetal heart (A–E), including one normal fetal heart (C) and five examples (A,B,D,E) of fetal four-chamber views that are abnormal, owing to perturbed flow distribution, in a setting of a normal central fibrous body. **A:** Four-chamber view of the heart of a fetus with PS. The right ventricle (RV) is thick walled and has a slightly diminutive right ventricular cavity. In the presence of PV stenosis and a competent tricuspid valve, the increased right ventricular afterload results in myocardial hypertrophy, whereas the decreased diastolic compliance of the hypertrophic myocardium results in increased right-to-left shunting at the level of the foramen ovale, with increased left ventricular (LV) diastolic filling volume and diminished right ventricular filling volume. **B:** Four-chamber view of the heart of a hydropic fetus with severe AS, left ventricular dilation, and fibroelastosis, with decreased systolic contraction. Severe mitral regurgitation resulted in marked left ventricular (LV) and left atrial (LA) dilation and premature closure of the foramen ovale. **C:** Normal four-chamber view of fetal heart demonstrating symmetrical right and left atria (RA, LA) and ventricles (RV, LV). **D:** Four-chamber view of fetal heart of a fetus with coarctation of the aorta. The right ventricle is disproportionately enlarged, whereas the left ventricle is relatively volume depleted. This is due to the abnormal distribution of blood flow, favoring outflow from the right ventricle at the expense of outflow from the left ventricle in this fetus with aortic arch hypoplasia. **E:** Four-chamber view of fetal heart near term. This image demonstrates the finding that disproportionate right ventricular dilation, while characteristic of flow redistribution in fetuses with coarctation of the Ao, is sensitive but not specific for this malformation. In this case, the disproportion between ventricular dimensions is not associated with aortic coarctation, but rather, with normal flow redistribution near term in a fetus with mild constriction of the ductus arteriosus, with resulting increased right ventricular afterload. This image was found in one of the patients in our series who was incorrectly suspected to have coarctation of the aorta, based on this finding.

Figure 27.4. A: Long-axis view of the LVOT. The anterior right ventricle (RV) is separated from the posterior left ventricle (LV) by the ventricular septum. The integrity of the anterior ventricular septum can be evaluated. The membranous and conoventricular septa are intact and are in fibrous continuity with the anterior wall of the ascending aorta (Ao). The anterior mitral valve leaflet is in fibrous continuity with the posterior aortic wall, resulting in commitment of the left ventricle to the ascending aorta. The left atrium is posterior to the ascending aorta. The subaortic region is unobstructed. The right pulmonary artery passes beneath the aortic arch. B: Long-axis view of the right ventricular outflow tract. The right and left ventricles (RV, LV) are separated by the intact ventricular septum. The main pulmonary artery (PA) arises above the conus and dives posteriorly to continue into the ductal arch. The main pulmonary artery is perpendicular to the ascending aorta, which passes vertically until the branch point between the innominate artery and the aortic arch.

Figure 27.5. Montage of six long-axis views of the fetal heart. A: Long-axis view of the LVOT of a fetus with pulmonary atresia with VSD. The ventricular septum is interposed between the left and right ventricles (LV, RV). The large ascending aorta (Ao) overrides a large, subaortic, conoventricular septal defect. The right ventricular outflow tract is not visualized in this view. B: Long-axis view of the LVOT in a fetus with d-TGA. The interventricular septum is intact. There is ventriculoarterial discordance, with the transposed ascending aorta (Ao) arising anteriorly from the right ventricle (RV) and the main pulmonary artery (PA) arising from the left ventricle. The parallel course of the great arteries is characteristic of transposition or malposition. C,D: Normal left (C) and right (D) ventricular outflow tracts. E: Long-axis view of the LVOT in a fetus with type I persistent truncus arteriosus. The common arterial trunk (Tr) overrides a large conoventricular septal defect. A common pulmonary artery (asterisk) arises from the left and posterior aspect of the common arterial trunk. F: Long-axis view of the LVOT of a fetus with Taussig-Bing double-outlet right ventricle. The parallel, d-malposed great arteries both arise from over the right ventricle, with the pulmonary artery overriding the subpulmonary VSD. The anterior aorta is much smaller than the posterior pulmonary artery. Further investigation demonstrated a hypoplastic aortic arch.

Figure 27.6. M-mode echocardiographic tracing recorded through aortic root of fetus with atrial ectopic tachycardia at 180 beats per minute. The aortic valve opening (v) corresponds to the mechanical response to electrical stimulation leading to ventricular myocardial contraction. Note that there is one atrial undulation (a) for each ventricular contraction.

cardiovascular compensation of given fetuses. They have suggested that this scoring system be used to predict the onset of cardiovascular decompensation in such fetuses (Fig. 27.11).

CONGENITAL HEART DISEASE AND ASSOCIATED ANOMALIES

The association of congenital heart disease with extracardiac malformations of the fetus and neonate is well recognized. In some cases, the genetic basis for these associations has been defined (9,10,65–68).

Increased nuchal fold thickness during the first trimester of pregnancy may be associated with a high incidence of congenital heart disease. In some cases, the increased nuchal thickness is related to karyotypic abnormalities such as Turner (XO) syndrome or trisomy 21 (69–74). In other cases, karyotype may be normal, and increased nuchal thickness is thought to relate to elevated fetal venous pressure from congestive heart failure. Increased first trimester fetal nuchal thickness is another screening method that has been used as an indication for detailed fetal echocardiographic study (17,75–83).

Typical associations do exist between specific congenital heart malformations, extracardiac malformations, and karyotypic abnormalities. These associations include atrioventricular septal (canal) defects, increased nuchal thickness, macroglossia, hypoplastic fifth metacarpal, duodenal atresia,

Figure 27.7. Color flow imaging demonstrating inferior vena caval (IVC) return to the fetal right atrium and aortic arch flow (Arch) into the descending thoracic aorta (DAo).

sandal foot, and trisomy 21; double-outlet right ventricle, intrauterine growth restriction, clinodactyly, rocker bottom feet, esophageal atresia, and trisomy 18; VSD, holoprosencephaly, intrauterine growth restriction, cleft lip and palate, and trisomy 13; and coarctation of the aorta, bicommissural aortic valve, cervical cystic hygroma, pedal edema, and Turner syndrome (XO). The association between conotruncal malformations and (del) 22q11.2, DiGeorge syndrome, and/or velocardiofacial syndrome has been well established (84–89).

We have found approximately 60% of fetuses presenting with complete, balanced, AVSD and previously undiagnosed karyotype to have trisomy 21. Approximately 20% of patients with complete AVSD have abnormalities of situs and spleen formation. The association of interrupted IVC, azygous continuation to the superior vena cava, intestinal malrotation, complete heart block, and/or agenesis of the gall bladder and extrahepatic biliary atresia are strongly suggestive of left atrial isomerism and polysplenia. On the other hand, the associated presence of double-outlet right ventricle, AVSD, PS or atresia, totally anomalous pulmonary venous connection, and intestinal malrotation are strongly suggestive of right atrial isomerism with asplenia (90–96). Such fetuses represent some of the most difficult cases to manage postnatally.

The frequent association of karyotypic abnormalities with congenital heart disease diagnosed during the second trimester (30.5%) has led us to recommend genetic diagnosis whenever congenital heart disease is diagnosed in the human fetus (10,65,66,97,98). Although many patients have been reticent to submit to the risks involved with amniocentesis, chorion villus sampling, or fetal umbilical blood sampling, especially if they have no intention of terminating the pregnancy, even if a karyotypic abnormality is found, or if the pregnancy has already progressed past the legal limit for abortion, we have still recommended such testing in selected cases. Although termination of pregnancy is a compelling and common reason for genetic testing, the knowledge of an associated genetic abnormality may serve to change the aggressiveness of tocolytic therapy for the treatment of premature labor or the aggressiveness of fetal monitoring and the use of cesarean delivery for fetal distress during labor in the mothers of such fetuses.

The frequent association of congenital heart disease (C), especially conotruncal malformations and abnormalities of the vertebrae (V), anus (A), trachea (T), esophagus (E), kidneys (R), and limbs (L) (VACTERL) should raise suspicions when congenital heart disease is diagnosed in fetuses with polyhydramnios (e.g., impeded fetal swallowing), oligohydramnios (impeded urine production), scoliosis, or limb reduction (99,100).

Another, increasingly common, indication for targeted echocardiographic imaging is the presence of intensely echogenic foci within the left ventricular cavity (Fig. 27.12). This finding is thought to relate to increased mineralization of the tips of the papillary muscles within the left ventricle and, in and of itself, does not appear to have short- or long-term clinical consequences. Until recently there was some debate about whether these echogenic foci are clinical markers for the presence of trisomy 21. A recent meta-analysis concluded that such foci increase the odds that a given pregnancy is complicated by the Down syndrome by a factor of five to six. It is recommended, therefore, that this factor be included in the risk calculation (e.g., along with traditional serum markers and nuchal translucency evaluation) for consideration of invasive genetic diagnosis for affected fetuses (101–111).

WHAT IS IT THAT PARENTS WANT TO KNOW?

The value of prenatal diagnosis can best be assessed in light of what parents expect from these studies. It would be easier

Figure 27.8. Series of figures demonstrating Doppler color flow analysis in fetuses with congenital heart disease. A: Retrograde flow in the ductus arteriosus (*Ductus*) of a fetus with complex congenital heart disease, including pulmonary atresia. B: Retrograde perfusion of the aortic arch (*Ao*) in a fetus with complex congenital heart disease including aortic arch hypoplasia. C: Left-to-right flow across the foramen ovale (*asterisks*) in a fetal patient with HLHS. LV, left ventricle; RV, right ventricle.

to cost account such studies if they had a clear-cut impact on neonatal survival or quality of survival. As we would see below, such an impact is difficult to demonstrate for many of these studies. On the other hand, there is little doubt that detailed prenatal diagnosis has an impact on prenatal counseling and on the process of obtaining informed consent from parents whose fetuses have complex congenital heart disease.

Our counseling process consists of a detailed description of the anatomic abnormalities in the fetus. This includes

abnormalities of the heart and cardiovascular system, as well as extracardiac abnormalities that may have been diagnosed. The details of neonatal care, including the timing, location, and mode of delivery; details of medical support, including the potential need for prostaglandin E_1 infusion for the maintenance of ductal patency; and the potential need for reparative or palliative surgery in the neonatal period are discussed. The details of neonatal and later surgical procedures are discussed, and the parents are given the opportunity to speak

Figure 27.9. Doppler tissue imaging velocities from lateral tricuspid valve ring (A) and Doppler flow-velocity waveforms from right ventricular inflow of normal midtrimester fetus (B). Note dominant a' and a waves. These waveforms are consistent with relatively restrictive fetal ventricular myocardium at this stage of development.

Figure 27.10. Schematic representation of idealized postnatal versus fetal capillary hemodynamics. The relationship between hydrostatic and plasma oncotic pressures and estimated interstitial tissue pressure result in a net outward pressure gradient of 1 mm Hg in the fetus, whereas in the postnatal cardiovascular system the net pressure gradient is 0. This explains the dependency of the fetal cardiovascular system on avid lymphatic drainage to prevent fetal edema and fluid third spacing.

with the pediatric cardiac surgeons, pediatric surgeons, and neonatologists who are likely to be involved in neonatal management.

In large part, parents care little about the detailed name or anatomic description of their child's anomaly. They are, most often, interested in learning what the short-, mid-, and long-term prospects for survival are. These are often related to associated anomalies, genetic syndromes, or underlying anatomy. From a purely anatomic perspective, the breakpoint in the continuum of disease severity, from 1 (minimal) to 10 (most severe), occurs at 8. Eight to ten on this scale represents lesions that are not reparable into a two-ventricular physiology, and will, by definition, require Fontan palliation and/or orthotopic transplantation.

The prospects for cardiac and neurodevelopmental outcome are discussed, and the parents are encouraged to ask questions of the physician management team and/or a team composed of parents of children with similar problems who have consented to be available, as requested.

DOES PRENATAL CARDIAC DIAGNOSIS MAKE A DIFFERENCE?

It has taken approximately a quarter-century of experience with prenatal cardiac diagnosis to demonstrate that such studies have a positive impact on survival (112–114). In fact, multiple studies that focused on the impact of prenatal diagnosis of HLHS appeared to suggest that prenatal diagnosis had a negative influence on short-term survival (49,115–128). This is almost certainly related to a weighting toward prenatal diagnosis in a sicker subpopulation of fetuses. A study undertaken at Yale during the early 1990s failed to demonstrate a survival advantage related to the prenatal diagnosis of congenital heart disease with single-ventricle physiology, whereas fetuses with lesions reparable into two ventricular systems appeared to enjoy a significant enhancement of survival prospects (10). This study also demonstrated a common experience with several other series in which it was noted that prenatal cardiac diagnosis, by facilitating anticipatory use of prostaglandin E_1 to prevent closure of the ductus arteriosus in neonates with critical impairment of systemic or pulmonary blood flow, allows affected fetuses to avoid neonatal acidemia (129–131). Although currently an unproven hypothesis, the potential neurodevelopmental advantage to be derived by the affected neonate who avoids acidemia may, in the long run, prove to be the most important long-term salutary effect of prenatal cardiac diagnosis (132). Among the individual cardiac lesions for which prenatal diagnosis has been suggested to impart a survival advantage are transposition of the great arteries (TGA), coarctation of the aorta, and HLHS. A review

of the experience in the latter series emphasizes the impact of prenatal diagnosis on the parental intention-to-treat decision-making process (10,49,122–124,127,133).

The Impact of Prenatal Cardiac Diagnosis on Planning for Delivery

A relatively unique consideration of the impact of prenatal cardiac diagnosis on outcomes that is not readily appreciated in reviews of surgical outcome for individual lesions relates to the options for site of delivery of these patients. It has been demonstrated that surgical survival for neonates with HLHS is directly related to the surgical volume of the individual surgical center (134). Prenatal diagnosis, by providing parents with the luxury of time to conduct research, may alter survival through alteration of the site of delivery and subsequent surgery. It is possible, if not likely, that the latter will exert a profound impact of prenatal cardiac diagnosis on postnatal survival.

With the possible exception of patients with associated extracardiac lesions (e.g., abdominal wall defects) that necessitate cesarean delivery (135), it is rare for the pediatric cardiologist to become involved in the decision making concerning mode of delivery. Possible exceptions include fetuses with cardiac rhythm disturbances that preclude effective intrapartum fetal heart rate monitoring. Such arrhythmias may include chaotic rhythms that confound the logic of external fetal heart rate monitors that calculate heart rate from instantaneous measurement of R-R intervals or regular tachyarrhythmias or bradyarrhythmias such as AF or complete heart block, where the heart rate may not vary with the alterations in sympathetic and parasympathetic tone that are associated with uterine contraction (10).

Cesarean delivery may be indicated in rare situations in which the coordinated care of the neonate requires the skills of multiple specialists who are assembled specifically at the time of delivery. In the year 2005, at the Morgan Stanley Children's Hospital of New York–Presbyterian we delivered four fetuses by cesarean section specifically for cardiac reasons. Two fetuses were delivered by cesarean section owing to prenatal identification of premature closure of the foramen ovale in fetuses with HLHS with secondary pulmonary venous obstruction, whereas one fetus was delivered by cesarean section to undergo cardiac surgery because of obstructed totally anomalous pulmonary venous return in a setting of right atrial isomerism, AVSD, double-outlet right ventricle with d-malposition of the great arteries, and pulmonary atresia. One fetus, with d-TGA and congenital diaphragmatic hernia, was delivered by cesarean section and immediately placed on extracorporeal membrane oxygenation (ECMO), pending surgical repair of diaphragmatic hernia and subsequent successful arterial switch repair of TGA.

	NORMAL	-1 POINT	-2 POINTS
Hydrops	None (2 pts)	Ascites <u>or</u> Pleural effusion <u>or</u> Pericardial effusion	Skin edema
Venous Doppler (Umbilical vein) (Ductus venosus)	 UV DV (2 pts)	 UV DV	 UV pulsations

Figure 27.11. Huhta's proposed Cardiovascular Profile Score.

It is unusual for neonates with congenital heart disease to require resuscitation in the delivery room. In such cases, there is usually an associated problem that interferes with adequate lung inflation at the time of the first breath. Such issues may arise in fetuses with associated pleural effusions,

Figure 27.12. Intensely echogenic focus associated with the anterolateral mitral papillary muscle. This does not represent a cardiac neoplasm, nor does it represent a structural malformation of the fetal heart. There has been a suggestion that such foci are associated with an increased odds ratio of associated fetal Down syndrome. The *arrow* points to an echogenic focus in the left ventricle.

in fetuses with associated congenital diaphragmatic hernia, or in fetuses in which marked cardiomegaly results in a mass effect and pulmonary hypoplasia (e.g., occasional cases of Ebstein malformation of the tricuspid valve or AS with marked mitral regurgitation). In fetuses with severe pulmonary venous obstruction, such as those with totally anomalous pulmonary venous drainage with obstruction (particularly common among fetuses with visceral heterotaxy and right atrial isomerism), congenital atresia of the common pulmonary vein, or in fetuses with HLHS and premature closure of the foramen ovale, gas exchange may be rendered inadequate by pulmonary edema. Doppler waveform analysis in the branch pulmonary veins may be predictive of critical pulmonary venous obstruction (Fig. 27.13). Fetuses with tetralogy of Fallot (TOF) and absent PV with aneurysmal pulmonary arteries may have inadequate ventilation owing to external airway compression with secondary tracheomalacia or bronchomalacia (Fig. 27.14).

REGIONAL BLOOD FLOW ANALYSIS AND FETAL CARDIOVASCULAR WELL-BEING

Techniques for the antenatal surveillance of the fetus are aimed at the detection of evidence of cardiovascular compromise secondary to hypoxemia and deterioration of acid-base balance (69,129,136–143). Blood flow within the placental circulation is normally characterized by low placental vascular resistance with no evidence of autoregulation within the placental vascular bed, whereas regional arterial flow in the fetal organ beds is finely tuned through local autoregulation. Impaired forward arterial flow is almost invariably associated with altered preload and with abnormalities of flow within the fetal central venous system, including the inferior vena cava (IVC), ductus venosus (DV), and umbilical vein (UV). Abnormalities of flow in these three locations may be used to predict acid-base status in growth-retarded fetuses (Fig. 27.15). Progressive deterioration in cardiac pump

Figure 27.13. To-and-fro flow pattern in pulmonary vein in a fetal patient with obstructed left ventricular inflow and outflow. This pattern is highly suggestive of severe pulmonary venous obstruction. This fetus is likely to have critical pulmonary insufficiency in the neonatal period. Such fetuses may require emergent pulmonary vein decompression in the neonatal period and have been subjected to efforts at atrial septal fenestration in utero.

function is associated with absent forward venous flow during atrial contraction or with atrial flow reversal in the central venous circulation. The finding of retrograde flow in the DV during atrial contraction is almost always associated with fetal acidemia, and diastolic notching of flow within the UV, especially with evidence of absent or reversed end-diastolic flow in the umbilical artery (UA), is a finding that presages fetal death if delivery is not accomplished within the ensuing 72 hours (Fig. 27.16) (144–149).

Ventricular–vascular coupling within a cardiovascular system based largely on massive blood flow through a low-resistance bed such as the placenta, with a propelling pump consisting of fetal myocardium, with limited preload and afterload reserve is markedly sensitive to alterations in placental resistance and/or to altered myocardial performance or intravascular volume (150). Elevation of placental vascular

Figure 27.14. Pulmonary regurgitation (asterisk) through the rudimentary PV structure in a fetus with TOF with absent PV results in dilation of the right ventricle (RV) and pulmonary artery (PA). Such fetuses are in danger of pulmonary insufficiency in the delivery room secondary to external compression of the major airways by the aneurysm-dilated main and proximal right pulmonary artery.

Figure 27.15. DV flow waveforms. A: Normal DV flow demonstrates high continuous antegrade flow during systole (s), diastole (d), and during atrial contraction (a). B: Retrograde DV flow during atrial contraction. This is a finding that is associated with progressive ventricular dysfunction, with increased end-systolic volume, and increased end-diastolic pressure.

resistance is typically accompanied by an increase in umbilical arterial pulsatility (difference between peak arterial and end-diastolic flow velocity), whereas enhanced perfusion (organ-sparing) of fetal organs is associated with decreased local resistance and decreased arterial pulsatility. Brain sparing has been demonstrated to be strongly predictive of perinatal

Figure 27.16. A: Simultaneous recording of UA and UV waveforms in normal fetus. Note the high end-diastolic velocity in the UA, characteristic of a low-resistance placental circulation. There is continuous antegrade flow in the UV. B: Umbilical arterial and venous flow in a fetus with paroxysmal polymorphic VT and hydrops fetalis. Note chaotic, rapid, undulating UA flow and marked umbilical venous notching associated with cannon a waves. The latter are associated with elevated systemic venous pressure, hydrops fetalis, and fetal acidosis.

morbidity in fetuses with intrauterine growth retardation and has been correlated with impaired cognitive outcome in children who were born as very preterm infants (151–153). It has been suggested that growth-restricted human fetuses with chronic cerebral hypoxemia and established brain-sparing centralization of blood flow may have limited capacity for further hyperperfusion in response to superimposed acute hypoxemia (154). Fouron et al. (155–157) have focused attention on the direction of blood flow in the aortic isthmus among patients with congenital heart disease. These workers have found that retrograde isthmus blood flow is correlated with impaired neurodevelopmental outcome, perhaps related to limited cerebral oxygen delivery. We have focused our attention on pulsed Doppler evidence of centralization of fetal blood flow as evidence of autoregulation of fetal cerebral blood flow in the presence of congenital cardiac malformations associated with impaired cerebral oxygen delivery owing to impaired cerebral arterial oxygen content or impaired cerebral blood flow volume (158). We have speculated that these alterations in blood flow may be associated with altered neurodevelopmental potential among these fetuses. Kaltman et al. (159) found similar cerebral flow redistribution among fetuses with right ventricular outflow obstruction, whereas Jouannic et al. (160) found similar cerebral flow redistribution among fetuses with TGA.

THE PRENATAL EVOLUTION OF CONGENITAL HEART DISEASE

The principal underlying Rudolph's concept that understanding fetal cardiovascular adaptation to congenital heart disease will provide insight into the transitional and neonatal circulation is that in the fetal heart form follows function. It was postulated for many years prior to the availability of ultrasound for the observation of progressive cardiovascular development in the presence of congenital heart disease that certain congenital cardiac malformations evolve through the course of pregnancy, with a tendency toward progressive chamber and blood vessel disproportion (1).

It has been demonstrated, for example, that pulmonary outflow obstruction in fetuses with TOF may progress in severity, even to the point of acquired pulmonary atresia, over the course of pregnancy (118,161,162). Aortic or pulmonary valvar stenosis may progress over the course of pregnancy into valvar atresia, and ventricular wall thickness may increase in concert with increased ventricular peak systolic pressure. Ventricular chamber development may be stunted by the development of endocardial fibroelastosis and diminished ventricular compliance through pregnancy (163). On the other hand, the onset of AV valve regurgitation, related to papillary muscle dysfunction or chordal rupture, may result in marked progressive ventricular and atrial chamber enlargement.

PRENATAL TREATMENT OF CONGENITAL HEART DISEASE

In 1992, Allan et al. reported an experience with a percutaneous technique for fetal aortic balloon valvuloplasty (164) involving needle puncture of the maternal abdomen, uterus, and fetal thorax, with direct catheterization of the fetal left ventricle by direct apical puncture and subsequent wire and catheter manipulation across the stenotic aortic valve. Four fetuses were subjected to this technique, with a single long-term survivor. That technique was devised against a background of appalling survival figures for neonates who were undergoing surgical

treatment for that lesion at that time. Interestingly, between the announcement of that procedure in the popular press and the appearance of the publication in the scientific literature, that same group declared a moratorium on the procedure, related in part to improved surgical and interventional catheterization results with neonates with AS (120). A subsequent publication described the world's experience with this technique and documented a 100% failure rate at several institutions (165), with the almost inexplicable conclusion that further investigation was merited to determine the potential role for the technique in the management of fetuses with congenital heart disease.

A decade later, the group from Boston Children's Hospital released to the press the results of a preliminary experience with the use of this same technique, which was being proposed as a means of preventing the evolution of severe fetal AS with associated left ventricular fibroelastosis into HLHS. This group has attempted to establish criteria for selection of candidates for this procedure and has preliminary data to suggest that in selected cases fetal balloon valvuloplasty may result in incremental aortic and left ventricular growth, and may result in adequate left heart development to obviate the need for Norwood-type palliation, with subsequent biventricular palliation of these patients. This group has suggested that retrograde perfusion of the aortic arch is one of the criteria that is predictive of hypoplastic left heart in patients who do not undergo palliation. Their experience suggests that successful aortic balloon valvuloplasty results in antegrade perfusion of the aortic arch and isthmus in these fetuses (112,166).

Tulzer et al. (167,168), from Austria, reported an experience with fetal percutaneous pulmonary balloon valvuloplasty, under ultrasound guidance, to alter the natural history of pulmonary atresia with intact ventricular septum. Their initial experience was undertaken to avoid the onset of hydrops fetalis. The potential for hydrops fetalis was assessed on the basis of the Cardiovascular Profile Score that was proposed by Huhta (63). Subsequent experience has suggested that pulmonary outflow obstruction is almost invariably associated with atrial flow reversal in the IVC and DV that may affect the cardiovascular performance score and unduly increase the prediction of subsequent hydrops fetalis. Several centers have subsequently reported successful PV dilation and biventricular management of fetuses who presented with pulmonary atresia and intact ventricular septum (169–171). Rigorous evaluation of the selection criteria and outcome of such fetuses has not been reported at this point.

The Boston Children's Hospital group has also reported a preliminary experience with percutaneous balloon dilation of the atrial septum, in an effort to palliate fetuses with HLHS and pulmonary venous obstruction secondary to premature stenosis or closure of the foramen ovale (112). This technique was devised to improve the results for the palliation of these fetuses, who may present with severe pulmonary hypertension and pulmonary lymphangiectasia. The experience reported to date suggests that needle perforation of the atrial septum, wire passage across the septum, and delivery of an angioplasty catheter with subsequent balloon septoplasty can be accomplished. This preliminary experience suggests that improvement in balloon technology will be required before the technique may be expected to result in a lasting fenestration of the atrial septum that is adequate to effect a positive impact on fetal physiology. This same group has recently reported successful coronary stent placement in the atrial septum of a fetus with HLHS. This fetus survived and subsequently underwent successful Norwood stage I palliation. A recent report describes the use of fetoscopy to place an intracardiac ultrasound catheter into the esophagus of a human fetus with HLHS to provide transesophageal imaging during an unsuccessful attempt to perform balloon septoplasty on a fetus with critical pulmonary venous obstruction (172).

Reports of the use of fetoscopy and laser fenestration of the atrial septum in such fetuses, for the management of AS, have emerged from Tampa (173). Ludomirsky et al. in St. Louis, are investigating the use of targeted ultrasound to create fenestrations of the fetal atrial septum. Scattered anecdotal reports of attempts to perform aortic and pulmonary balloon valvuloplasty procedures have surfaced at national and international cardiology meetings.

The overall results of these procedures ideally should be collected, analyzed, and reported in a critical fashion, lest the pediatric cardiology community repeat the hard lessons learned by the maternal-fetal medicine community during the past 25 years. The latter have had a broad experience with fetal therapy, and have seen several promising techniques capture the imagination of the medical community and the popular press, only to be abandoned later after disappointing functional outcomes were found on follow-up of surviving infants. Such techniques were based on a seemingly sound understanding of physiology and on a genuine desire to be of help to these fetuses. These included procedures for fetal exteriorization for repair of diaphragmatic hernia and for palliation of urinary tract obstruction, and percutaneous cerebral ventriculoamniotic shunting for palliation of obstructive hydrocephalus (113,174–183).

THE CURRENT ROLE OF FETAL ECHOCARDIOGRAPHY

While fetal echocardiography and fetal cardiology have been incorporated into many pediatric cardiology programs during the past two decades, the role of fetal cardiology varies considerably from location to location. In many cases, the role of fetal cardiology is dependent upon the relationship that exists between maternal-fetal medicine and pediatric cardiology in the institution, and whether individual institutions have obstetric and neonatal services housed under the same roof.

We have reviewed the role that prenatal cardiac diagnosis has had during the last 4 calendar years (2007 to 2010) at the Morgan Stanley Children's Hospital of the Columbia University Medical Center campus of New York–Presbyterian Hospital. This service represents a highly evolved fetal cardiology service, with an extremely active Department of Obstetrics and Gynecology, with a maternal-fetal-medicine division that has been actively involved in the performance of detailed fetal echocardiography for many years. Similarly, the Pediatric Echocardiography service of the Morgan Stanley Children's Hospital has been extremely aggressive in its approach to fetal cardiology, and the integration of these patients into the neonatal cardiology and cardiovascular surgery service.

Unlike the case at many centers, where the pediatric cardiology service provides “screening” services for fetal congenital heart disease, the service at our hospital is based on a model in which the pregnant woman is seen, almost exclusively, by the obstetrical service, until a high-risk indication for a targeted fetal echocardiogram is identified (Table 27.1). While services that perform screening studies usually find evidence of fetal cardiovascular disease in approximately 10% to 15% of scans (Table 27.2), with the predominant indication for scan being a previous family history of congenital heart disease, we have a very different experience (270, 271).

In 2007 to 2010, our laboratory detected 615 fetuses with congenital cardiovascular abnormalities among 2,828 fetuses undergoing fetal echocardiography (yield 22%). There were 31 false positives (cases of relative right heart enlargement and suspected coarctation of the aorta including six fetuses with left-sided congenital diaphragmatic hernia with rightward deviation of the heart and mediastinum). Fourteen false-negative cases were documented, including 11 small VSDs

that did not require surgical or medical management and three moderate to large VSDs that required surgery in the first months of life.

Of the 615 patients with congenital heart disease follow-up is complete for 90%. Sixty patients (10%) have been lost to follow-up and an additional 15 were known to have been liveborn at outside hospitals. Of 396 babies known to have been liveborn, 64% (184) underwent surgery during the first 6 months of life (249 at Columbia University Medical Center and 3 at outside hospitals). Ten additional babies underwent interventional catheterization procedures at Columbia. Of these babies 88 (33%) have undergone additional surgery within the first 6 months of life, and nine are <6 months of age as of the time of writing this chapter.

Of the 615 cases of correctly identified congenital heart disease, the “categories” of abnormality, in descending order of frequency, consisted of conotruncal malformations (213 [35%]), left heart obstructive lesions (126 [20%]), left-to-right shunt lesions (106 [17%]), including 29 complete AVSD, right heart obstructions (51 [8%]), visceral heterotaxia (33 [5%]), double-inlet left ventricle (18 [3%]), aortic arch anomalies (27 [4%]), Ebstein malformation of the tricuspid valve (14 [2%]), single ventricle variants (17 [3%]), absent PV syndrome with intact ventricular septum (2 [$<1\%$]), complex conjoined hearts in thoracopagus twins (2 [$<1\%$]), and other, one-of-a-kind anomalies (6 [1%]) (Table 27.3).

One hundred thirty (21%) patients either underwent termination of pregnancy (102) or chose nonintervention (“compassionate care”) (28) for their offspring. The diagnoses of these fetuses, presented in Table 27.4, were weighted toward severe anomalies such as HLHS and visceral heterotaxia, and those with chromosomal and severe extracardiac abnormalities.

Twenty-eight patients suffered intrauterine fetal demise (Table 27.5). These included 10 with documented chromosomal anomalies including five fetuses with trisomy 18, three with trisomy 21, and two with trisomy 13. Two fetuses with demise had additional severe anomalies but no chromosomal study, including one with a complex single ventricle and absent kidneys, and one with double-outlet right ventricle and Pentalogy of Cantrell. Four fetuses who suffered intrauterine demise had normal chromosomes with an extracardiac fetal anomaly or a maternal abnormality, including three fetuses with hypoplastic left heart variants (one with an absent stomach, one with prune belly syndrome, and one with maternal protein S deficiency), and one fetus with persistent truncus arteriosus and placental insufficiency. Three fetuses had intrauterine demise associated with complete AV block, including two with left atrial isomerism, and one with atrial and VSDs. The remaining nine fetuses with intrauterine demise had congenital heart disease but no additional anomalies, including four fetuses with Ebstein malformation of the tricuspid valve (comprising 29% of fetuses with Ebstein malformation seen), two fetuses with pulmonary atresia and intact ventricular septum (one of whom also had left ventricular outflow obstruction and no karyotype, the other with severe cardiomegaly and a normal karyotype), two fetuses with AVSD and hydrops fetalis (one complete AVSD with no chromosomal study and one unbalanced, LV-dominant AVSD with normal chromosomes), and one fetus with absent PV syndrome and intact ventricular septum.

Of the 615 fetuses with congenital cardiac malformations 327 (53%) underwent prenatal karyotyping. Seventy (21%) of these fetuses had identifiable genetic syndromes while 169 patients underwent only postnatal genetic testing, of which 17 (10%) had an abnormality. Chromosomal abnormalities included 39 cases of trisomy 21 (15 with complete AVSD, and 13 with TOF), 13 with trisomy 18 (seven with VSD, four with double-outlet right ventricle, one with complete AVSD, one with AS), four with Turner Syndrome (two with bicommissural aortic valve, one with HLHS, and one with a small VSD).

TABLE 27.3 Congenital Heart Disease Diagnoses in Fetuses 2007–2010 (*n* = 615)

Diagnosis	2007	2008	2009	2010	Total
Conotruncal Malformations

TABLE 27.4

Terminations of Pregnancy or Compassionate Noninterventional Care for Fetuses with Congenital Heart Disease 2007–2010 (*n* = 130)

Terminations of Pregnancy (<i>n</i> = 102)		
Cardiac Lesion	<i>n</i>	Genetic or Extracardiac Abnormality
Hypoplastic Left Heart Syndrome	13	None
Tetralogy of Fallot	13	22q11 deletion (1), Trisomy 21 (1), XYY (1)
VSD	11	Trisomy 18 (3), Trisomy 13 (1), Chromosome 13 deletion (1), Cardiomyopathy (1), CDH (1), CNS (1), skeletal (2), renal (1)
Heterotaxy	9	CDH and renal (1)
Double-outlet right ventricle (DORV)	6	Trisomy 13 (1)
AVSD	5	Trisomy 21 (4)
Complex Single Ventricle	4	CNS (1)
Tricuspid Atresia	4	None
Pulmonary atresia/Intact ventricular septum	4	Cleft lip/palate (1)
Double Inlet LV	4	CDH (1)
Pulmonary atresia/VSD/PDA	4	None
Interrupted arch/VSD	3	22q11 deletion (1)
Truncus arteriosus	3	22q11 deletion (2)
Ebstein's	3	None
HLHS variant	3	CNS and renal (1)
PA/VSD/MAPCAs	2	22q11 deletion (1)
Coarctation/VSD	2	Limb/Body wall complex (1)
TOF/Absent PV syndrome	2	22q11 deletion (1)
d-TGA	1	None
Hypoplastic aortic arch	1	CNS and skeletal (1)
Aortic stenosis	1	Trisomy 18(1)
TOF/AVSD	1	Trisomy 21 (1)
Shones	1	CNS (1)
Absent PV syndrome/IVS	1	None
Complex conjoined hearts	1	Conjoined twins (1)
Total	102	
Compassionate (Hospice) Care (<i>n</i> = 28)		
Cardiac Lesion	<i>n</i>	Genetic or Extracardiac Anomalies or Other Issues
DORV	5	Trisomy 18 (2), CHARGE (1), CNS anomaly (1), Perinatal CNS insult (1)
VSD	4	Trisomy 18 (2), Trisomy 21 + hydrops (1), CHARGE (1)
HLHS variant	3	16q24 deletion (1), Chromosome 8 deletion (1), Abnormal head vessel anatomy (1)
HLHS	3	Intact atrial septum/Premature triplet (1), Poor RV function + TR (1), Compassionate care given at OSH (1)
Heterotaxy	3	Obstructive pulmonary venous return as component of cardiac lesion (2), Heart block + hydrops (1)
Single Ventricle Variant	1	Chromosome 4 deletion
AVSD with coarctation of aorta (CoA)	1	Trisomy 18
Pulmonary atresia/intact ventricular septum	1	Severe cardiomyopathy
PA/VSD/MAPCAs	1	22q11 deletion, premature twin

TABLE 27.4

Terminations of Pregnancy or Compassionate Noninterventional Care for Fetuses with Congenital Heart Disease 2007–2010 (*n* = 130) (Continued)

Cardiac Lesion	<i>n</i>	Genetic or Extracardiac Anomalies or Other Issues
TOF	1	Renal disease, anhydramnios
Critical pulmonary stenosis	1	Congenital diaphragmatic hernia
Ebstein anomaly	1	Hydrops
PA/VSD/PDA	1	Trisomy 13
Shone's	1	Restrictive Foramen Ovale
Complex conjoined hearts	1	Thoracopagus twins
Total	28	

Eighteen patients were found to have Chromosome 22q11.2 microdeletion (five with truncus arteriosus communis; four with pulmonary atresia, VSD, and major aortopulmonary collateral arteries (MAPCAs); three with TOF; three with interrupted aortic arch (IAA) with VSD; one with hypoplastic left heart with a cervical aortic arch; one with TOF with absent PV syndrome; and one with pulmonary atresia with VSD and patent ductus arteriosus [PDA]). An additional nine patients had unique abnormalities consisting of a chromosomal deletion, gain, inversion, or translocation. There were two patients who underwent prenatal karyotyping but were not diagnosed to have genetic syndromes until postnatal genetic testing took place (one with a 22q11.2 microdeletion and one with an XrX ring chromosome). Table 27.6 reviews the results of chromosomal testing on this cohort of patients.

One hundred thirty-seven fetuses were identified who had congenital cardiac malformations and associated extracardiac malformations. The latter included 63 fetuses with multiple extracardiac anomalies, and 74 with single extracardiac anomalies, including 6 with congenital diaphragmatic hernia, 18 with central nervous system anomalies, 15 with renal anomalies, 9 with gastrointestinal anomalies, 6 with skeletal anomalies, and 6 with abdominal wall defects.

Indications for detailed fetal echocardiographic study are presented in Table 27.7. Note the marked predominance of “suspected congenital heart disease” in this list, and the relative infrequency of “family history of congenital heart disease.” We attribute this, and the paucity of cases of associated chromosomal abnormalities to the maturity of the screening program within maternal–fetal medicine at our hospital.

In a more recent review of our experience (185), we gained important perspectives that have led us to reexamine our mission. During the 4-year interval from 2004 to 2008, 439 neonates underwent cardiothoracic surgery at our institution. Of these 294 (67%) were diagnosed prenatally. The majority underwent surgery with a Severity Score of 3 to 6. Eighteen of these patients underwent emergency surgery, and a total of three required ECMO support.

A detailed comparison between the prenatally and postnatally diagnosed infants was performed. Not surprisingly, single ventricle variants, including HLHS, were significantly more likely to be diagnosed prenatally. This, alone, was responsible for the significantly higher Surgical Severity Score among the neonates who were diagnosed prenatally. While double-outlet right ventricle was significantly more likely to be diagnosed prenatally, the same did not hold for TOF. TGA was significantly more likely to be diagnosed postnatally, and total

anomalous pulmonary venous connection was, by far, more frequently a postnatal finding than a prenatal diagnosis.

Somewhat surprisingly, we found no difference between arterial pH and highest measured serum lactate between the prenatal and postnatal diagnosis groups. The prenatal diagnosis group was significantly more premature at birth (37.9 ± 2 weeks vs. 38.6 ± 2 weeks). This almost certainly reflects our policy of suggesting elective induction of labor for fetuses with potential ductal dependency who live at any significant distance from our center. This may have deleterious effects on the development of the brain, which has been found to lag in development in many fetuses with severe forms of congenital heart disease. We are reexamining this policy, to avoid elective deliveries prior to 39 weeks gestation. Another finding, which may be unique to our institution, is that the average age at surgery was 6 to 7 days, regardless of whether the infant was diagnosed prenatally or postnatally (in fact, the prenatal group [7 {5 to 8} days] waited significantly longer for surgery than the postnatal diagnosis group [6 {5 to 9} days]). This held, even when the groups were stratified according to cardiac diagnosis. This may be related to the much higher propensity for surgery to be postponed for the infants who were diagnosed prenatally (22.8% vs. 11.7%, $p = 0.006$). The latter is disturbing, and suggests that length of stay and total hospital costs could be impacted significantly for the prenatal group if we are more assiduous in scheduling surgery upon admission for delivery of the prenatal diagnosis group.

FETAL CARDIAC ARRHYTHMIAS

Fetal cardiac arrhythmias have been recognized with increasing frequency during the past several years and in general have been associated with a greater degree of maternal and physician anxiety than they deserve. Most irregularities of fetal cardiac rhythm represent isolated extrasystoles, which frequently present as a perceived skipping of fetal heart beats. Extrasystoles are significant only because of the potential for an appropriately timed extrasystole to initiate sustained reentry tachycardia in the presence of an appropriate anatomic substrate involving an accessory conduction pathway or a region of scar with unidirectional block and decremental conduction. The statistical likelihood of this occurring in the fetal or immediate neonatal period is in the range of 0.5% to 2%. The most common, important, sustained fetal arrhythmias are orthodromic reciprocating supraventricular tachycardia (SVT), AF

TABLE 27.5 Fetal CHD with Intrauterine Fetal Demise 2007–2010 (*n* = 28)

Cardiac Diagnosis	Other Findings	Karyotype
Absent PV Syndrome/IVS	Hydrops fetalis	None
ASD and VSD	Complete heart block	None
AVSD	Hydrops fetalis	None
AVSD	None	Trisomy 21
AVSD	None	Trisomy 21
AVSD	Oligohydramnios	Trisomy 21
AVSD, LV-dominant	Hydrops fetalis	Normal
AVSD, LV-dominant with AS, LA isomerism	Complete heart block	Normal
AVC/DORV/MGV, LA isomerism	Complete heart block, renal anomaly, Hydrops fetalis	Normal
Complex single ventricle	Absent kidneys, anhydramnios	None
DORV	Duodenal atresia	Trisomy 18
DORV	CNS, renal, and skeletal anomalies	Trisomy 18
DORV	Arnold Chiari, neural tube defect, renal and skeletal anomalies, Hydrops fetalis	Trisomy 13
DORV/MA/AA	Absent stomach	Normal
DORV/MGV	Congenital diaphragmatic hernia, skeletal anomalies	Trisomy 18
DORV/PA with Ectopia Cordis	Pentalogy of Cantrell	None
Ebstein malformation	Hydrops fetalis	None
Ebstein malformation	Hydrops fetalis	None
Ebstein malformation	Hydrops fetalis	Normal
Ebstein malformation	None	None
HLHS (Mitral stenosis/Aortic atresia)	Prune belly syndrome	Normal
HLHS (Mitral stenosis/Aortic atresia)	Maternal Protein S deficiency, on Lovenox	Normal
PA/IVS, also LVOT obstruction	Hydrops fetalis	None
PA/IVS	Severe cardiomegaly	Normal
Pulmonary atresia/VSD	Cleft lip and palate, cerebral and genital anomalies, hydrops fetalis	Trisomy 13
Truncus arteriosus	Placental insufficiency	Normal
VSD (large inlet)	Skeletal anomalies	Trisomy 18
VSD (large inlet)	Congenital diaphragmatic hernia, Skeletal anomalies, hydrops	Trisomy 18

with varying degrees of AV block, and severe bradycardia associated with complete AV block (10).

Nineteen patients were found to have sustained fetal arrhythmias during 2004 and 2005. Nine fetuses had sustained atrial premature contractions. None of these fetuses went on to develop sustained SVT, and none received prenatal therapy. Ten patients with sustained arrhythmias received in utero therapy and went on to live birth with normal neonatal cardiovascular function. These included two fetuses with prolonged AV conduction (1) or complete heart block (1) in the presence of positive maternal titers against Ro or La antibodies. The first fetus received dexamethasone as part of a multicenter study and was born with normal AV conduction. The second of these fetuses required cardiac pacing in the neonatal period, owing to recalcitrant complete heart block. Two fetuses, with left atrial isomerism, complete AVSD, hydrops fetalis, and complete heart block were classified as heterotaxy syndrome and were not included in the group presenting with

sustained arrhythmia as the chief complaint. One patient with HLHS and intermittent SVT was classified among fetuses with congenital heart disease as the primary diagnosis.

The other eight fetuses had sustained supraventricular tachyarrhythmias, including AF (1), ectopic atrial tachycardia (EAT) (2), and orthodromic reciprocating tachycardia (5). They responded to antiarrhythmic therapy protocols that contained digoxin, alone or in combination with propranolol, sotalol, or flecainide (Table 27.8).

In the presence of sustained fetal tachyarrhythmia, it is common for the fetus to develop hydrops fetalis (10). The latter arises because of the development of venous hypertension in the presence of significant atrial backflow into the IVC circulation. The increase in hydrostatic pressure results in a net increase in extravasation of fluid into the interstitial space that is not adequately compensated by fetal lymphatic drainage. It is not uncommon, therefore, for hydrops fetalis to develop despite maintenance of normal or nearly normal

TABLE 27.6

Chromosomal Anomalies of Fetuses with Congenital Heart Disease 2007–2010 (*n* = 89)

systolic ventricular shortening. Sustained fetal tachycardia and hydrops fetalis have been associated with neonatal hypoalbuminemia and hyperbilirubinemia, even weeks following resolution of the tachycardia and fetal anasarca (186). This is probably attributable to high IVC pressure and associated hepatic dysfunction, with decreased albumin production and biliary stasis. The decreased albumin production, resulting in decreased fetal and neonatal serum oncotic pressure, contributes both to the production of fetal edema and anasarca and to the considerable delay that is often encountered between arrhythmia control and resolution of hydrops fetalis.

Bradycardia associated with complete AV block may result from autoimmune damage to the AV conduction system, related to transplacental passage of anti-Ro (SS-A) or La (SS-B)

antibodies. Such mothers may have clinical symptoms of systemic lupus erythematosus or Sjögren syndrome, although in many young women, the detection of fetal heart block may be the first evidence of an elevated antibody titer in an otherwise asymptomatic mother (187–194).

Bradycardia owing to complete AV block may be diagnosed in fetuses with negative maternal antibody titers. Many of these fetuses have complex congenital cardiac disease with malformations involving the development of the central fibrous portion of the heart (e.g., AV discordant connections in congenitally corrected TGA or left atrial isomerism with ambiguous AV connections). Complete heart block must be distinguished from sinus bradycardia, which may be associated with fetal hypoxemia, or from blocked atrial bigeminy, in which every second atrial contraction is so premature that the AV node is still refractory because of the previous sinus beat and therefore unable to conduct the premature contraction (95,195).

These three forms of bradycardia can be distinguished from one another through careful evaluation of atrial rhythm. In sinus bradycardia, there is a one-to-one relationship between the slow atrial rate and the equal ventricular response rate. In complete heart block, the atrial rate is regular and exceeds the slower, regular, idioventricular rhythm. In blocked atrial bigeminy, the atrial rate is regularly irregular, with paired beating between the conducted beat and the blocked premature atrial beat, which is not conducted. Magnetocardiographic

TABLE 27.8 Clinically Important Fetal Arrhythmias Encountered during 2004–2005 (*n* = 13)

Pt. no.	Arrhythmia	Cardiac Structure	Cardiac Function	Medication(s)	Comments	Outcome
1	Orthodromic reciprocating tachycardia (ORT)	Normal	Normal	Digoxin		NSR (A/W)
2	Persistent junctional reciprocating tachycardia (PJRT)	Normal	Decreased (hydrops fetalis)	Digoxin; flecainide; propranolol		NSR Function normalized; hydrops resolved (A/W)
3	ORT (intermittent)	Normal	Normal	Propranolol		NSR (A/W)
4	ORT	Normal	Normal	Digoxin		NSR (A/W)
5	AF	Normal	Decreased (hydrops fetalis)	Digoxin; sotalol		NSR function normalized; hydrops resolved (A/W)
6	EAT	Normal	Decreased	Digoxin; propranolol	In utero control	Neonatal recurrence resolved with amiodarone/propranolol (A/W)
7	ORT	Normal	Decreased (hydrops fetalis)	Digoxin; sotalol		NSR function normalized; hydrops resolved (A/W)
8	ORT	Normal	Normal	Digoxin; flecainide	Therapy started elsewhere	NSR (A/W)
9	ORT	HLHS	Decreased RV function			Termination of pregnancy
10	Complete AV block	LA isomerism complex AVSD	Decreased hydrops fetalis			Termination of pregnancy
11	Complete AV block	LA isomerism complex AVSD	Decreased hydrops fetalis			Termination of pregnancy
12	Complete AV block	Normal	Decreased	Dexamethasone	Maternal lupus	Epicardial VVI pacemaker (A/W)
13	Primary AV block	Normal	Normal	Dexamethasone	Maternal anti-SS-A; anti-SS-B	NSR (A/W)

studies of fetal patients with recurrent episodes of SVT have suggested that many of the premature atrial beats that occur in these fetuses are echo beats that reenter the atrium via accessory pathways but are not conducted back into the ventricle through the AV node (196).

Analysis and Treatment of Fetal Cardiac Arrhythmias

In the absence of reliable electrocardiographic recordings of fetal atrial and ventricular electrical activity, M-mode, pulsed Doppler, and color-encoded M-mode echocardiographic recordings of mechanical and flow events are used to time and sequence the electrical activation underlying these events (Fig. 27.17) (10,52,197–217). Rein et al. (218) described the use of Doppler tissue imaging to time the mechanical activation sequence of the atria and ventricles to analyze cardiac rhythm using a ladder diagram or kinetocardiogram to provide similar information. Recent reports have demonstrated that magnetocardiography may provide important information regarding fetal atrial activation and the morphology of fetal QRS complexes, QT intervals, and T-wave morphology. This procedure is laborious, requires special equipment and magnetic shielding, and is not widely available, but may well emerge as the preferable means of analyzing clinically significant fetal arrhythmias (196,219–223).

Fetal Antiarrhythmic Therapy

The existence of techniques for the analysis and treatment of fetal cardiac arrhythmias is insufficient justification to expose a mother and fetus to the potential hazards of antiarrhythmic therapy. Fetal therapy offers the potential for dramatic success, but also has the potential for catastrophic consequences for two patients at once. The management schema for such patients should be predicated on an understanding of the natural history of the arrhythmia, a precise knowledge of the electrophysiologic basis for the arrhythmia, and a detailed appreciation of the pharmacokinetics and pharmacology of antiarrhythmic agents in the fetus, mother, and placenta. These must be factored in a commonsense risk/benefit analysis. Neonatal risk increases proportionately with the degree of prematurity and lung immaturity at the time of the initial diagnosis. This must be balanced against the degree of cardiovascular compromise accompanying the arrhythmia. In the absence of extreme prematurity, or without evidence of severe fetal hemodynamic compromise (e.g., hydrops fetalis), fetal intervention is difficult to justify.

Analysis of Fetal Tachyarrhythmias

Figure 27.18 presents a suggested algorithm for the analysis and treatment of fetal tachyarrhythmias. If tachycardia is

Figure 27.17. Color-encoded M-mode echocardiogram. The M-mode tracing imparts temporal resolution to the color flow recording. In this orientation, diastolic filling of the fetal ventricle is toward the transducer, resulting in the biphasic e and a waves, whereas the ejection into the aorta is away from the transducer and is inscribed as the aliased blue/cyan image.

associated with AV dissociation or is sustained in the presence of varying degrees of AV block, AV reentry tachycardia (AVRT) (either orthodromic or antidromic) or AV nodal reentry tachycardia (AVNRT) cannot be the underlying electrophysiologic mechanism of the tachycardia, since those tachycardias are characterized by a 1:1 AV contraction sequence, driven by a circus movement of electrical energy at the AV junction.

If there is AV dissociation, with a ventricular rate in excess of atrial rate (A:V ratio $<1:1$), one may assume that the tachycardia arises below the bundle of His and does not depolarize the atrium in a retrograde direction with a 1:1 ratio. The latter is characteristic of ventricular tachycardia (VT) or junctional ectopic tachycardia (JET). When there is some degree of AV block with an A:V ratio of $>1:1$, one may be dealing with intra-atrial reentry tachycardia (IART), ectopic atrial tachycardia (EAT), multifocal atrial tachycardia (MAT), atrial flutter (AF), or atrial fibrillation. In the presence of these arrhythmias, the atrial rate exceeds that of the ventricles, with the relationship dictated by the degree of AV block.

In the presence of a strict 1:1 A:V ratio, we evaluate the ventriculoatrial (VA) interval. Using simultaneous recordings of central venous and arterial pulsed Doppler flow waveforms, the time sequence of atrial and ventricular electrical activation can be discerned. Such recordings can be obtained by placement of the Doppler sample volume to overlap the fetal superior vena cava and ascending aorta (224) or fetal right pulmonary artery and right pulmonary vein (Fig. 27.19) (225). The AV mechanical interval may be used as a surrogate of electrocardiographic PR interval, and the VA time interval may also be calculated.

In the presence of a very short VA interval or one slightly >70 ms, the most likely electrophysiologic mechanism of the tachycardia is orthodromic AVRT or AVNRT. If the A:V ratio is $>1:1$ with a regular atrial tachycardia, the likely diagnosis is AF or IART. Depending on gestational age, the likelihood of pulmonary maturity, and the presence or absence of hydrops fetalis, we may or may not consider the use of in utero antiarrhythmic treatment to the fetus. A fetus with unsustained tachycardia or without hydrops fetalis is not in immediate danger and is not likely to be offered prenatal therapy. On the other hand, in the presence of sustained tachyarrhythmia, with hydrops fetalis, the risk/benefit analysis tips in the direction of in utero therapy.

Intrauterine Antitachyarrhythmic Therapy

In the face of severe prematurity, immediate delivery for postnatal treatment may not be a logical option. The frequent association of hydrops fetalis with sustained SVT and the dismal prognosis for such fetuses and neonates in a setting of extreme prematurity may justify vigorous efforts at in utero therapy, if such treatment can be offered at a tolerably low risk to the mother. Even a moderate risk to the fetus could be justified in this setting, in light of the poor prognosis for the neonate if the arrhythmia and hydrops fetalis are unremitting. The decision regarding the institution of fetal treatment should consider the following: (a) the fetal hemodynamic state (Is there hydrops fetalis?), (b) the potential risks to mother and fetus inherent in fetal treatment, (c) availability of facilities for monitoring of mother and fetus, and (d) willingness of the mother to submit to such treatment and monitoring.

Many antiarrhythmic drugs have a narrow therapeutic margin and may be associated with significant toxicity, including proarrhythmic potential. Only the Vaughn-Williams class II (β -blocker) agents appear to lack the potential for late proarrhythmic mortality. Type IA or type III agents, alone or in combination with medications that interfere with drug metabolism through the cytochrome P-450 pathway, may precipitate polymorphic VT (*torsades de pointes*). Type IC agents such as flecainide may cause QRS prolongation and VT that is recalcitrant to treatment. The absence of a readily available technique to monitor fetal QTc or QRS duration during antiarrhythmic therapy constitutes a fundamental hazard associated with fetal antiarrhythmic therapy.

Prior to the initiation of antiarrhythmic therapy, the therapeutic goal should be established. In some circumstances, rate control may provide an adequate opportunity to recover fetal cardiovascular function, whereas in many cases complete control of the arrhythmia is necessary to allow resolution of hydrops fetalis.

The literature is filled with many reports touting the virtues of different antiarrhythmic agents for the control of fetal tachyarrhythmias (10,226–242). Few of these reports discussed medication choices based on a detailed analysis of the electrophysiologic mechanism of the arrhythmia. The algorithm that we present is based on a sequential analysis of arrhythmia mechanism modeled after the framework suggested by Walsh et al. (243). The suggested sequence of drug administration has evolved considerably over the past several years and has been influenced by personal experience and the literature. This is offered as a step-off point for consideration by the reader when fetal antitachycardia treatment is anticipated. Just as different cardiac centers use differing medical regimens for the same arrhythmia in infants and children, it is expected that fetal antiarrhythmic treatment protocols will be individualized, based on local experience with specific antiarrhythmic medications. A rational approach to the treatment of these patients should consider the nature of the arrhythmia, the hemodynamic impact of the rhythm disturbance, and the pharmacology and pharmacokinetics of the maternal-placental-fetal unit. We have settled on a simplified treatment protocol, focusing on the administration of digoxin, propranolol, sotalol, and amiodarone. We have had limited experience with the use of flecainide in the fetus, although some centers have found the latter to be a safe and effective agent for the treatment of some fetal arrhythmias. We have made a team approach to the administration of antiarrhythmic treatment to the pregnant woman. This team includes maternal-fetal medicine, pediatric cardiology, and adult cardiology specialists to focus on the care of these complex patients. Such teams should devise their own treatment plans, which may differ at individual medical centers or for individual patients.

Figure 27.18. Suggested algorithm for the analysis and treatment of fetal tachyarrhythmias.

Figure 27.19. Simultaneous inscription of flow waveforms from the right upper pulmonary artery (*above the baseline*) and right upper pulmonary vein (*below the baseline*). The undulations of the pulmonary vein representing atrial contraction (a) are related to the timing of the upstroke of the systolic ejection into the branch pulmonary artery (v). The atrioventricular (a-V) and ventriculoatrial (V-a) conduction times may be measured and related to the electrical events underlying the mechanical responses that result in the flow events recorded in this image.

Treatment of the Fetus with Bradycardia

The most important sustained fetal bradyarrhythmia is congenital complete heart block. These fetuses may develop hydrops fetalis. The latter may occur in the subgroup of fetuses with associated congenital heart disease. The association of fetal heart failure with congenital heart block, with or without congenital heart disease, represents an absolute indication for electrical pacemaker therapy in the neonate. In the fetus, the association of complete heart block and hydrops fetalis is dire. When associated with congenital heart disease, the outcome is almost invariably fatal, with or without fetal therapy (195).

The initial report of the use of electrical pacemaker therapy for the treatment of fetal congenital heart block involved a fetus presenting with heart block in the absence of congenital heart disease (244). This fetus presumably incurred immune complex-mediated damage to the fetal conduction system and myocardium. There was severe bradycardia and hydrops fetalis. In desperation, the treating physicians placed a pacing catheter within the fetal heart via percutaneous puncture of the maternal abdomen, uterus, fetal thorax, and ventricular wall. Fetal ventricular capture was demonstrated, without clinical improvement. Subsequent attempts to use similar pacing systems have been, likewise, unsuccessful.

Laboratory models of complete heart block have been created in fetal lambs, with subsequent resolution of hydrops fetalis following fetal exteriorization and surgical implantation of permanent pacemakers connected to epicardial pacing leads (245). An attempt to implant a pacemaker in this fashion in a human fetus was unsuccessful. Although it may well be that some human fetuses with heart block and hydrops fetalis have deteriorated solely because of bradycardia, we are concerned that some neonates do not respond to pacing alone. This subgroup of patients may have immune-mediated damage to the contractile elements of the heart from the same mechanism that damaged the fetal conduction system (246–250). Although it has been demonstrated that the administration of β -mimetic agents to the pregnant woman may increase the intrinsic ventricular rate of the fetus by 50%, there has been no consistent evidence that such treatment ameliorates hydrops fetalis in affected fetuses (184, 251–253).

A preliminary experience in our laboratory with the administration of absorbable corticosteroid to pregnant women whose fetuses had developed high-grade second-degree or recent-onset third-degree heart block in the presence of high titers of anti-SS-A or SS-B antibodies suggested that such treat-

Figure 27.20. Rendered STIC image of aortic and ductal arches obtained from STIC dataset recorded with B-mode documentation of cardiac and vessel blood flow. (Reproduced from Gonçalves LF, Lee W, Espinosa J, et al. How do we do it? ment might halt the progression or even reverse the damage to the conduction tissue (10). This study spawned a multicenter investigation designed to evaluate the impact of maternally administered corticosteroid on echocardiographically estimated fetal AV conduction intervals (254–261). Some centers have adopted steroid therapy for the routine treatment of fetuses with antibody-mediated congenital complete heart block, based on improved mortality statistics in the current era compared with historical controls (262–265). The results of the multicenter study noted above are likely to provide an important insight into the appropriateness of such therapy (266).

Three-Dimensional Fetal Echocardiographic Imaging

During the few years that have elapsed since the last edition of this textbook, there has been great interest in the use of 3- and 4-D ultrasound for the examination of the fetal heart. Different technologies have evolved for the acquisition of 4-D datasets that allow online and postprocessed images of the cardiac chambers and great vessels. Interest has been expressed by the maternal-fetal-medicine community in the use of such datasets for remote analysis and for automated multislice images of the fetal heart in order to facilitate screening for congenital heart disease. The two most commonly used technologies are Spatiotemporal Image Correlation (STIC) and real-time 4-D imaging using 2-D matrix-array transducers (Fig. 27.20).

STIC imaging requires synchronization of spatial and temporal imaging by serially constructing a 4-D dataset from multiple 2-D images constituting a single cardiac cycle. The 2-D anatomic images may be combined with color or

Figure 27.21. STIC image of four-chamber view of fetal heart is seen in the left-sided panel. The yellow dot at the crux of the ventricular septum is the focal point around which the image is “spun” in a clockwise fashion to demonstrate the relationship between the ventricular septum and the anterior wall of the aorta in the left ventricular long-axis view of the outflow tract. (Reproduced from Devore GR, Polanco B, Sklansky MS, et al. The ‘spin’ technique: a new method for examination of the fetal outflow tracts using three-dimensional ultrasound. *Ultrasound Obstet Gynecol* 2004;24(1):72–82, with permission from John Wiley and Sons.)

power Doppler flow information to increase the accuracy of the imaging process.

Using STIC imaging, it is possible to examine the heart in three orthogonal planes and to gradually slice through the azimuthal plane in each view (267). Postprocessing allows rendering, which may view the flow within the heart and great vessels with the body and heart rendered transparent. Using inversion imaging, it is possible to demonstrate B-flow within the heart and blood vessels. Such images may allow detailed evaluation of vascular anomalies (Fig. 27.21). Devore et al. (268) demonstrated the utility of visualizing the outflow tracts in detail in each plane by rotating (“spinning”) the image of the individual 2-D view of the outflow portion of the heart around chosen point within the outflow tract (Fig. 27.22).

It remains to be seen whether STIC imaging fulfills its potential for increasing the sensitivity and specificity of screening programs for fetal congenital heart disease. The automation

of outflow tract imaging is an attractive alternative, but recent studies (269) have suggested that this imaging results in satisfactory views in only 70% to 83% of fetuses at 18 to 22 weeks gestation. Certainly, in order to obtain adequate STIC analysis of the fetal heart, it is essential that satisfactory four-chamber visualization of the heart serve as the foundation for the sequential dissection and rotation of the 4-D dataset.

We have found that 3- and 4-D imaging is particularly useful for evaluating the spatial relationship of the great arteries in fetuses with conotruncal malformations. As noted above, since such fetuses constitute the largest single group of fetal anomalies in our laboratory, we have found ourselves increasingly dependent upon STIC imaging. Another important role for STIC imaging has been for the evaluation of the AV valves and their chordal attachments. The latter are particularly useful in evaluating patients with single ventricular or AVSD variations.

Figure 27.22. Reconstructed 3-D tomogram of the two ventricles. Reconstruction is from STIC 4-D dataset. Mitral valve (MV) and tricuspid valve (TV) are labeled. (Reproduced from Gonçalves LF, Lee W, Espinosa J, et al. How do we do it? Practical advice on imaging-based techniques and investigations. *Ultrasound Obstet Gynecol* 2006;27(3):336–348, with permission from John Wiley and Sons.)

Septal Defects

CHAPTER

28

Atrial Septal Defects

Ritu Sachdeva

INTRODUCTION

Atrial septal defects (ASD) originate at particular sites in the atrial septum and are named according to their embryonic origin. The most common occurs in the central part of the atrial septum in the region of fossa ovalis (secundum ASD). Others include those in the region of endocardial cushion (primum ASD), in the sinus venosus septum (sinus venosus ASD), and in the region of ostium of coronary sinus (coronary sinus ASD). In this chapter, we also address patent foramen ovale (PFO), which is a normal interatrial communication present in fetal life that may persist in adults. Ostium primum ASD is discussed in Chapter 29 since it is a part of the spectrum of atrioventricular septal defects (AVSD).

INCIDENCE

ASDs constitute 8% to 10% of congenital heart defects in children. The incidence of ASDs has been estimated to be 56 per 100,000 live births (1). The recent estimates are much higher (100 per 100,000 live births), likely due to increased recognition of ASDs in this era of the common use of echocardiography (2). The female:male ratio for secundum ASDs is 2:1, but for the sinus venosus ASDs it is 1:1 (3,4). Secundum ASDs constitute approximately 75% of ASDs, followed by ostium primum ASD (20%) and sinus venosus ASD (5%) (5). Coronary sinus (CS) ASDs more often are seen in association

with heterotaxy syndromes and systemic venous anomalies, and isolated CS ASDs are rare (<1%).

GENETIC AND ENVIRONMENTAL RISK FACTORS

Although most ASDs occur sporadically, familial modes of inheritance have been reported. The risk of congenital heart disease in offspring of a woman with a sporadic ASD is estimated to be 8% to 10% (6). ASDs may be related to mutations in either regulatory genes or their target sarcomeric genes. Heterozygous mutations in the transcription factor NKX2.5/CSX were among the first found in families with autosomal dominant transmission of secundum ASDs (7). Mutations in other transcription factors such as TBX5, GATA4, GATA6, and TBX20 also have been associated with secundum ASDs (7–11). TBX5 mutations also are responsible for Holt-Oram syndrome, which is an autosomal dominant syndrome characterized by secundum ASD, anomalies of the upper extremities, and atrioventricular (AV) conduction delay (12). A locus on chromosome 14q12 with a missense mutation in alpha-myosin heavy chain (MYH6), a structural protein expressed at high levels in the developing atria, has been linked to dominantly inherited ASD (13). Secundum ASDs also have been reported in association with cardiomyopathies that have resulted from mutations in sarcomeric genes (14,15). In ASDs associated with prolonged AV conduction, an autosomal dominant pattern of inheritance has been reported (16). Secundum ASDs

also are associated with other syndromes such as Noonan, Down, Klinefelter, Williams, Kabuki, Goldenhar, and Ellis-van Creveld. In addition to genetic factors, maternal diseases and exposure to environmental risk factors may play a role in development of ASDs (17). These factors include pregestational diabetes, phenylketonuria, influenza and exposure to retinoids, nonsteroidal anti-inflammatory drugs, anticonvulsants, thalidomide, smoking, and alcohol (17–19).

PATHOGENESIS AND ANATOMIC FEATURES

During embryogenesis, the primitive atrium undergoes a complex septation process (Fig 28.1) (20). In the fourth week of embryonic life, the septum primum appears as a thin-walled sagittal fold in the middle of the common atrium and grows inferiorly toward the endocardial cushion. The opening between the leading edge of the septum primum and the endocardial cushion is called the ostium primum. Before complete closure of the ostium primum, tissue reabsorption occurs in the superior portion of the septum primum resulting in another opening called the ostium secundum. This occurs during the fifth and sixth week of embryonic life. Concurrently, an anterosuperior infolding of the atrial roof develops to the right of the septum primum, called the septum secundum that is concave shaped with a superior and inferior limb. The inferior limb fuses with the lowermost part of the atrial septum to join the endocardial cushion, thus separating the inferior portions of the two atria. The thick muscular ridge of the superior limb forms an incomplete partition that overlies the ostium secundum resulting in an opening called the foramen ovale. The septum secundum thus forms the concave-shaped superior margin of the fossa ovalis, called the limbus of fossa ovalis (annulus ovalis) and the septum primum forms the valve of fossa ovalis. During fetal life, inferior vena caval flow from the placenta is deflected toward the foramen ovale by the eustachian valve, and then blood is

directed from the right atrium to the left atrium via the foramen ovale. This fetal interatrial communication (the PFO) normally closes after birth as a result of fusion of the septum primum and septum secundum. However, it may persist in 25% to 30% of adults where it is probe patent with a competent valve. In some cases, the valve of fossa ovalis is incompetent, either congenitally or acquired due to elevated right or left atrial pressures allowing interatrial shunting across the foramen.

The atrial septal anatomy and location of various types of ASDs are shown in Figure 28.2. Secundum ASDs occur in the central part of the atrial septum (fossa ovalis) as a result of deficient valve tissue, ectopic or excessive resorption of septum primum, or deficient growth of septum secundum (Fig. 28.3). Such defects result in an enlarged ostium secundum. These defects usually are single, but rarely can occur as multiple atrial septal fenestrations.

Sinus venosus defects occur outside the margins of the fossa ovalis, in relation to the venous connections of the right atrium (Fig. 28.4). The right horn of sinus venosus incorporates the right superior vena cava (SVC) and inferior vena cava (IVC) into the right atrium. Ectopic or incomplete resorption of the sinus venosus results in deficiency of the wall that separates the right pulmonary veins from the SVC, IVC, and the right atrium resulting in a sinus venosus ASD (21). Some argue that these should be termed partial anomalous pulmonary venous return to the SVC. The interatrial communication in these defects is, in fact, the orifice of the unroofed right pulmonary vein and is not a true defect in the atrial septum per se. (21) Most commonly, the sinus venosus ASDs are related to the SVC where blood from the right upper and/or middle pulmonary veins is directed into SVC or the right atrium. Less frequently, a similar defect can occur inferior to the fossa ovalis in relation to the IVC and the right lower pulmonary venous orifice. This defect often has been termed an IVC-type sinus venosus ASD, although direct involvement of the IVC almost never occurs. Hence, the term sinus venosus defect of right atrial type is preferred (21).

Figure 28.1. Schematic diagram showing embryogenesis of atrial septum. LA, left atrium; LV, left ventricle; PFO, patent foramen ovale; RA, right atrium; RV, right ventricle. (Modified from Van Mierop LHS. Embryology of the atrioventricular canal region and pathogenesis of endocardial cushion defects. In: Feldt RH, McGoon DC, Ongley PA, et al., eds. *Atrioventricular Canal Defects*. Philadelphia, PA: WB Saunders, 1976:1–12, with permission.)

Figure 28.2. A: Anatomy of the atrial septum. View from the right atrial side. B: View from the left atrial side. The interatrial septum (IAS) is outlined by the dotted lines. It is formed by the limbus of the fossa ovalis on the right atrial side and the valve of the fossa ovalis toward the left. The aortic root indents the right atrial free wall anterosuperiorly as the torus aorticus (TA). C: Cross section of the heart in a 4-chamber view. The IAS formed by the limbus and valve of fossa ovalis lies between the right and left atria (RA, LA). The atrioventricular septum (AVS) lies between the RA and left ventricle (LV). D: Schematic diagram showing the location of various types of ASDs: (a) Secundum; (b) Primum; (c) Sinus venosus; (d) Coronary sinus. IVC, inferior vena cava; IVS, interventricular septum; MV, mitral valve; PT, pulmonary trunk; RAA, right atrial appendage; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve. (Reprinted by permission of the Mayo Foundation.)

The left horn of the sinus venosus forms the CS. The CS defect (unroofed CS) results from failure of the wall between the left atrium and CS to develop. There may be complete or partial unroofing of the CS resulting in direct communication with the left atrium (Fig. 28.5). Almost always, this anomaly is associated with a left SVC. A rare variation consists of complete absence of the CS rather than unroofing, along with a defect in the expected location of the ostium of CS. In such defects, blood from the left SVC directly enters the left atrium. Kirklin and Barratt-Boyes (5) classified the unroofed CS defects as type I, completely unroofed with LSVC; type II, completely unroofed without LSVC; type III, partially unroofed midportion; and type IV, partially unroofed terminal portion.

ASSOCIATED CARDIOVASCULAR ANOMALIES

Interatrial communications can occur in isolation, but often are associated with other congenital heart defects. The presence of an interatrial communication may be crucial for survival in some such defects such as hypoplastic left heart syndrome, D-transposition of great arteries, tricuspid atresia, and total anomalous pulmonary venous return. Partial anomalous pulmonary

venous return is present in almost 90% of patients with sinus venosus ASDs and, more rarely, can occur with secundum ASDs. Although valvular pulmonary stenosis frequently has been associated with ASDs, the increased gradient across the pulmonary valve may be flow related and not necessarily due to an abnormal valve per se. CS ASDs commonly are associated with a persistent left SVC. Aside from congenital heart defects, secundum ASDs also have been reported in association with noncompaction and apical hypertrophic cardiomyopathy (14,15).

Lutembacher Syndrome

Lutembacher syndrome is the association of an ASD with mitral stenosis. Unlike the original description by Lutembacher, where the mitral stenosis was considered to be congenital in origin, the current consensus is that it is of rheumatic origin (22). As a result of the mitral stenosis, the left-to-right shunting across the ASD is augmented. The ASD usually is large and unrestrictive. Therefore, the magnitude of the atrial level shunt is directly related to the degree of obstruction at the mitral valve. Rarely, when the ASD is restrictive, the left-to-right shunt is continuous due to significant pressure difference across the atrial septum during the entire cardiac cycle.

Figure 28.3. Secundum ASD occurs in the region of fossa ovalis. A: Right atrial view. B: Left atrial view. C: Four-chamber view, showing comparison of a heart with large secundum ASD (arrows) with a normal heart (toward the right). The right atrium (RA) and right ventricle (RV) are significantly enlarged in the heart with the ASD. D: Schematic diagram showing a left-to-right shunt across ASD, which becomes right-to-left with development of pulmonary vascular disease. Ao, aorta; LAA, left atrial appendage; IVC, inferior vena cava; MV, mitral valve; PT, pulmonary trunk; RAA, right atrial appendage; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve. Figure 28.5. Coronary sinus atrial septal defect (ASD). A: Right atrial view. B: Left atrial view. The defect is at the site of the CS ostium, anterior and inferior to the fossa ovalis (FO). A persistent left superior vena cava (LSVC) joins the left atrial wall (LA). IVC, inferior vena cava; MV, mitral valve; RV, right ventricle; SVC, superior vena cava; TV, tricuspid valve. Reprinted by permission of the Mayo Foundation.

PATHOPHYSIOLOGY

During fetal life, the majority of the blood reaching the left atrium comes via the foramen ovale since there is minimal flow to the lungs. After birth, the lungs expand and the pulmonary blood flow increases. The increased pulmonary venous return to the left atrium results in the left atrial pressure exceeding the right atrial pressure causing functional closure of the foramen ovale. Intrauterine physiology is not altered in the presence of an ASD, but unlike the PFO, the ASD does not close with the hemodynamic changes that occur following birth. The physiologic consequences of an ASD depend on the magnitude and duration of the shunt and its interaction with the pulmonary vascular bed. The primary determinant of the magnitude and direction of the shunt is the relative compliance of the ventricles. During the neonatal transition period as the pulmonary vascular resistance drops and the right ventricular wall becomes thinner and hence more compliant than that of the left ventricle, there is an increase in left-to-right shunting. Catheter-based studies on flow dynamics in ASD provide insight into the circulatory pattern during the various phases of cardiac cycle. Maximum left-to-right shunting occurs during diastole when all four cardiac chambers are in communication. Atrial contraction further augments this shunt. A small right-to-left shunt, predominantly from IVC blood can occur during early diastole or during onset of systole. The magnitude and amount of shunting varies with the respiratory cycle. During inspiration when the intrathoracic pressure is decreased, there is a decrease in the left-to-right shunt across the ASD. Conversely, during expiration, when the intrathoracic pressure is increased, there is an increase in the left-to-right shunt.

Moderate-to-large left-to-right shunts across an ASD result in volume overload and dilation of the right atrium and ventricle (Fig. 28.3). The tricuspid and pulmonary annuli may dilate and become incompetent. The volume-overloaded right ventricle alters the diastolic configuration of the left ventricle with septal bowing toward the left. Occasionally, the abnormal left ventricular geometry may result in prolapse of the

mitral valve or superior systolic motion of the mitral leaflet (23). As a result of the increased flow into the lungs, the pulmonary arteries, capillaries, and the veins are dilated and there can be flow-related pulmonary artery hypertension. Over time this can lead to medial hypertrophy of pulmonary arteries and muscularization of the arterioles resulting in pulmonary vascular obstructive disease (24,25). With severe pulmonary vascular obstructive disease, patients develop Eisenmenger syndrome as the atrial level shunt becomes right-to-left, resulting in cyanosis (Fig. 28.3).

CLINICAL PRESENTATION

History

Most patients with ASD are asymptomatic and may remain undiagnosed until later in life. They may come to medical attention due to abnormal auscultatory findings or diagnostic studies such as ECG, chest radiograph, or echocardiogram. Very rarely, some infants with ASD may present with features of pulmonary overcirculation, recurrent respiratory infections, and failure to thrive. The mechanism of heart failure in these infants is not well understood since the hemodynamics are quite similar to those who are asymptomatic. Some have proposed rapid remodeling and thinning of the pulmonary vascular bed to be the reason for this early presentation (26). Additionally, one should carefully evaluate mitral anatomy and function since mitral stenosis or regurgitation can augment atrial shunting. Despite repair of ASD in these patients, there may not be any significant improvement in their symptoms (27). Older children may present with symptoms of mild fatigue and dyspnea that may worsen with age. In adults, worsening of clinical condition has been attributed to various factors such as a decrease in left ventricular compliance secondary to coronary artery disease and hypertension, which, in turn, results in increased left-to-right shunt, right ventricular

failure, atrial arrhythmias, and elevated pulmonary artery pressure. Patients who develop Eisenmenger syndrome (reversal of the left-to-right shunt due to pulmonary hypertension) may present with cyanosis and syncope with exertion.

Physical Examination

Phenotypic features of various syndromes associated with ASD may be notable. The most common syndrome known to be associated with ostium secundum ASD is the Holt-Oram syndrome. In this syndrome, the thumb is hypoplastic and in some cases may be rudimentary or absent. Additionally, the metacarpals may be small or absent and the radius may be absent. The thumb may resemble a finger.

In patients with long-standing large left-to-right shunt, there is a left precordial bulge. Palpation reveals a prominent right ventricular impulse felt along the lower left sternal border and the subcostal area. In normal persons, splitting of S_2 has a normal variation with respiration. During inspiration, negative intrathoracic pressure causes increased venous return into the right side of the heart, which in turn causes the pulmonary valve to stay open for a longer duration in ventricular systole causing a normal delay in the pulmonary valve closure component of S_2 . During expiration, the positive intrathoracic pressure reduces the venous return to the right side of the heart, resulting in an earlier closure of pulmonary valve. The auscultatory hallmark of ASD is wide, fixed splitting of the second heart sound (S_2). This means that the aortic and pulmonary components of S_2 are widely separated during expiration and demonstrate little or no variation in degree of splitting during inspiration or with Valsalva maneuver. S_2 is “widely split” due to a delay in closure of the pulmonary valve resulting from prolonged emptying of the volume-overloaded right ventricle and increased pulmonary vascular capacitance leading to low pulmonary impedance and, therefore, a long “hangout interval” after the end of right ventricular systole. The S_2 is “fixed” since the increased right ventricular stroke volume does not vary much with respiration.

A systolic ejection murmur can be heard in the left upper parasternal area. The murmur is due to increased flow across the pulmonary valve. This murmur begins shortly after S_1 and is crescendo-decrescendo, reaching its peak in early to midsystole and ending before S_2 . When this murmur is loud, it can indicate a large shunt or associated pulmonary valve stenosis

(a systolic ejection click usually is present when the pulmonary valve is truly stenotic). When there is a large left-to-right shunt, a middiastolic murmur can be heard due to excessive flow across the tricuspid valve. This murmur is short, soft, low to medium in frequency, and localized to the left lower parasternal area. Rarely, a diastolic murmur may result from pulmonary regurgitation as a result of an exceptionally large pulmonary trunk that dilates the valve annulus.

Most patients are acyanotic. However, cyanosis can be seen in those with pulmonary hypertension, significant right ventricular outflow tract obstruction, or in rare cases of a large eustachian valve directing IVC blood into the left atrium via the ASD. Patients with pulmonary hypertension and a right-to-left atrial level shunt are cyanotic and have auscultatory findings that are different from those of patients with an ASD without pulmonary hypertension. The jugular venous pulse has a dominant “A” wave resulting from increased force of right atrial contraction. The large “A” waves result in presystolic distention of the right ventricle resulting in a fourth heart sound. The pulmonary component of S_2 is loud and prominent. The wide fixed splitting of S_2 and tricuspid flow murmur disappear and the midsystolic pulmonary flow murmur is replaced by a softer and shorter murmur. A high-frequency early diastolic murmur (Graham Steell murmur) of pulmonary regurgitation can be heard due to pulmonary valve incompetence resulting from pulmonary hypertension. Also, a holosystolic S_1 coincident murmur of tricuspid regurgitation heard best at the right lower sternal border can develop.

DIAGNOSTIC EVALUATION

Electrocardiogram and Electrophysiology

ECG findings depend on the type and size of the ASD. In patients with a small left-to-right shunt and no right atrial or ventricular dilation, the ECG is normal. With a significant left-to-right shunt, an rSR' pattern occurs in the right precordial leads indicating right ventricular volume overload (Fig. 28.6). There often is slight prolongation of the QRS complex with slurring of the terminal R', and the terminal forces are directed to the right, superiorly and anteriorly. Other features include right axis deviation and tall P waves reflecting right atrial enlargement. In almost 50% of patients

Figure 28.6. ECG in a 4-year-old patient with large secundum ASD showing rSR' pattern in lead V1 and V2 and terminal widening on S in lead V6 indicating right ventricular volume overload.

with sinus venosus ASD, a frontal plane P wave axis of <30 degrees is seen (4). In most patients with ASD, the frontal plane QRS axis is between $+95$ and $+170$ degrees. Ostium primum ASD can be distinguished from other forms of ASDs by the presence of a counterclockwise loop and left axis deviation. Rhythm usually is sinus in children. However, older patients, usually beyond the third decade of life, can have junctional rhythm or atrial arrhythmias such as atrial fibrillation or flutter (28). With the advent of pulmonary hypertension, the rSR' pattern in the right precordial leads is replaced by Q waves and tall monophasic R waves with deeply inverted T waves.

Electrophysiologic studies have demonstrated a significant age-related incidence of sinus node dysfunction that may begin in early childhood (29,30). These patients have prolonged corrected sinus node recovery times and sinoatrial conduction times (31). However, these findings are not significant clinically and the resting and ambulatory ECGs in these patients are normal. AV node dysfunction is less common than sinus node dysfunction. Electrophysiologic studies in such cases show a prolonged A-H interval or an AV node Wenckebach periodicity at slow atrial pacing rates. First-degree AV block can occur in older individuals as a result of intraatrial H-V conduction delay and in patients with a rare autosomal dominant form of secundum ASDs (16).

Chest X-Ray

A small shunt across the ASD generally results in a normal-appearing chest x-ray. Cardiomegaly, due to right atrial and right ventricular enlargement, and increased pulmonary vascular markings extending to the periphery are seen in patients with significant shunts. (Fig. 28.7). The dilated right ventricle occupies the apex and forms an acute angulation with the left hemidiaphragm in the anteroposterior projection and obliterates the retrosternal space in the lateral view. Dilation of the right ventricular outflow tract may cause smooth continuity with the enlarged main pulmonary artery. The proximal branch pulmonary arteries, especially the right pulmonary

Figure 28.7. Chest x-ray of a 5-year-old patient with a sinus venosus ASD. The x-ray shows cardiomegaly with right atrial prominence, increased pulmonary vascular markings, and prominent main pulmonary artery.

artery, also are dilated. The left atrial and left ventricular sizes are normal. If pulmonary hypertension develops, the increased peripheral pulmonary arterial vascularity is replaced by oligemic lung fields.

Echocardiogram

The echocardiogram is instrumental in defining the type of ASD, its size, the degree of shunting, its effect on the right-sided chambers of the heart, associated lesions, and estimations of right ventricular pressure. These echocardiographic findings help in determining the appropriate intervention.

Transthoracic Imaging

TWO-DIMENSIONAL IMAGING AND M-MODE

An ASD can be visualized from the subcostal, parasternal, and apical views. Subcostal views provide the best profile of the atrial septum since the ultrasound beam is perpendicular to it. However, subcostal windows may be suboptimal in older or obese patients. In apical views, a “drop-out” may be seen in the thin septal region of the fossa ovalis since the ultrasound beam is parallel to it. This can give a false appearance of an ASD.

The type of ASD can be determined by defining its location. PFO and secundum ASDs are located in the region of fossa ovalis, that is, the midatrial septal region (Fig. 28.8). A PFO is guarded by a flap valve on the left side and limbus of fossa ovalis to the right. A PFO can be differentiated from a secundum ASD by this overlap of septal tissue. Ostium primum ASDs are located between the anteroinferior margin of the fossa ovalis and AV valves. Sinus venosus defects are seen superiorly at the junction of SVC with the right atrium (Fig. 28.9). These defects are best seen from the subcostal short-axis or high right parasternal views as a communication between the atria where the right upper pulmonary vein and SVC are usually seen. The right pulmonary artery is seen in cross-section immediately above the ASD. Subcostal long-axis and parasternal short-axis views are useful in evaluating sinus venosus ASDs of the right atrial type which appear as a posteroinferior atrial defect with a deficient posterior margin (Fig. 28.9). Anomalous drainage of right middle and lower pulmonary vein can be seen best in the parasternal short-axis view. For CS defects, a large ostium of the CS is seen as an inferior interatrial communication, just above and anterior to the entry of IVC into the right atrium. Absence of the CS indicates complete unroofing. In partial unroofing, parts of the wall between the CS and the left atrium can be identified.

The enlarged right atrium, right ventricle, and pulmonary arteries also are seen on 2-D imaging. The volume-overloaded right ventricle causes diastolic flattening and paradoxical motion of the interventricular septum (Fig. 28.10). Associated anomalies such as pulmonary stenosis, mitral valve prolapse, and anomalous pulmonary venous return also should be evaluated using 2-D imaging. M-mode imaging of the ventricles will show an enlarged right ventricle and paradoxical septal motion (Fig. 28.10).

DOPPLER

Using color Doppler, one can visualize the shunt across the ASD (Fig. 28.8). This shunt usually is left-to-right, but in patients with elevated pulmonary artery pressure, a bidirectional shunt or a right-to-left shunt can be seen. Pulsed-wave Doppler shows interatrial shunting in late systole and early diastole. Since the pressure gradient across the atrial septum is minimal when these defects are nonrestrictive, low-velocity flow is noted using Doppler. Commonly, a qualitative

Figure 28.8. Echocardiography delineation of defects in the region of fossa ovalis. D: A pulsed-wave Doppler showing a left-to-right shunt across the ASD with phasic changes. LA, left atrium; RA, right atrium.

assessment of the shunt across the ASD is done by direct visualization of the shunt using color Doppler and its effect on the right-sided cardiac chambers. However, a quantitative assessment of the pulmonary to systemic blood flow ratio ($Q_p:Q_s$) also can be made. For this, the time velocity integrals obtained by tracing the pulsed-wave Doppler of pulmonary and aortic outflow are multiplied by the area of pulmonary and aortic valve, respectively. This has been shown to have a close correlation with the $Q_p:Q_s$ measured invasively by oximetry during cardiac catheterization (32). Presence of right ventricular outflow tract obstruction, semilunar valve insufficiency, and patent ductus arteriosus limit the use of this method (33).

A large left-to-right shunt may result in a flow-related peak gradient of as much as 30 mmHg across the pulmonary valve. However, with higher gradients, one must suspect associated pulmonary valvular stenosis. Progressive tricuspid regurgitation resulting from tricuspid annular dilation and lack of coaptation of leaflets can be seen with significant right ventricular dilation. Doppler assessment for estimating pulmonary artery pressure can be performed by measuring the tricuspid and pulmonary regurgitant jets and applying the modified Bernoulli equation to calculate transvalve gradients and adding estimated right atrial pressure and right ventricular end-diastolic pressure, respectively. Development of pulmonary hypertension results in worsening of tricuspid and pulmonary regurgitation. In addition, the main and proximal pulmonary arteries further dilate. The right

ventricle becomes hypertrophied, and its systolic function starts deteriorating.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

A transesophageal echocardiogram (TEE) is useful for evaluation of ASD when transthoracic images are inconclusive due to poor windows or unusual location of the defect. TEE can be particularly useful to detect a sinus venosus ASD, which easily can be missed using transthoracic imaging. In addition, it frequently is used as a monitoring adjunct for operative and percutaneous closure of ASD. Due to the close proximity of the transducer to the cardiac structures, transesophageal imaging allows better spatial resolution and superior images of the atrial septum compared with transthoracic imaging (Fig. 28.11).

CONTRAST ECHOCARDIOGRAPHY

Intravenous contrast using injection of agitated saline during transthoracic or transesophageal echocardiographic imaging can be used to confirm the shunting across an ASD or PFO. A left-to-right shunt is seen as a negative contrast washout into the right atrium, when the right atrium is opacified with contrast. A right-to-left shunt is detected by the presence of microbubbles in the left atrium and ventricle, and this effect can be augmented by performing a simultaneous Valsalva maneuver. In the presence of an unroofed CS, injection of contrast in the left arm will result in microbubbles in the left atrium before it opacifies the right atrium.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Imaging the ASD using 2-D echocardiography is based on limited number of orthogonal planes and could result in underestimation of the size of the ASD and its surrounding rims. With the availability of real-time 3-D echocardiography, an en face view of the entire atrial septum can be obtained, thus allowing better morphologic delineation of the ASD and its surrounding structures (34). This information is helpful in determining whether or not closure of the ASD can be accomplished with a transcatheter device (35). Furthermore, 3-D transesophageal echo now is being used not only to delineate anatomic features of ASD but also for guiding device closure during the procedure (Fig. 28.12) (36–38).

INTRACARDIAC ECHOCARDIOGRAPHY

Intracardiac echocardiography using an ultrasound catheter has been shown to be a safe alternative to transesophageal echocardiography for assisting in device closure of ASDs (39–42). It provides excellent 2-D and color-Doppler imaging of the interatrial septum and the surrounding structures. This technique has the advantage of eliminating the need for general anesthesia

and additional personnel to perform transesophageal echocardiography. However, due to the large size of the sheath required to insert the catheter, its use in smaller children is limited (42).

Cardiac Catheterization

In the current era cardiac catheterization seldom is indicated for diagnosis of ASDs unless pulmonary vascular disease is suspected. Angiography can be helpful in diagnosing associated lesions such as partial anomalous pulmonary venous return or mitral stenosis. During catheterization, a step-up in oxygen saturations in the right atrium will be noted in the presence of an atrial level left-to-right shunt. An increase in saturations of 10% or more from SVC and IVC in a single blood sample series or an increase of 5% in two series indicates the presence of an atrial level shunt. Similar results also can be obtained in the presence of a left ventricle to right atrial shunt, a ventricular septal defect-related tricuspid insufficiency, AVSDs, systemic arteriovenous fistula, or anomalous pulmonary venous return to the right atrium. Detection of a CS type of ASD can be challenging. Continuous oximetry using a fiberoptic

catheter pull-back in the CS has been employed to diagnosis a left-to-right shunting across such ASDs (43).

$Q_p:Q_s$ can be calculated using the standard Fick equation or indicator dilution technique. In the absence of any other major cardiac anomalies, the presence of a small left-to-right shunt ($Q_p:Q_s < 1.5$) is considered hemodynamically insignificant. When the $Q_p:Q_s$ is ≥ 1.5 , the shunt is considered significant.

Direct measurement of intracardiac and pulmonary artery pressure can be performed during catheterization, and pulmonary vascular resistance can be calculated. In the presence of a large defect, there is minimal gradient between the two atria and there can be a flow-related gradient across the pulmonary valve as high as 30 mm Hg. In cases of pulmonary hypertension, acute response to pulmonary vasodilators such as nitric oxide and oxygen generally has been used to assess the reversibility and make decisions regarding closure.

Angiography just outside the orifice of right upper pulmonary vein in a cranially angulated left anterior oblique projec-

tion is ideal for optimal visualization of location of the ASD (44). Injection into the main pulmonary artery will demonstrate pulmonary venous anatomy and shunt across the atrial septum, but is not ideal for determining the size and location of the ASD. A CS type of ASD can be diagnosed by injecting contrast selectively into the left SVC, pulmonary vein, or left atrium (45).

Other Imaging Modalities: CT/MRI

If the findings on echocardiography are uncertain, computerized tomography (CT) or magnetic resonance imaging (MRI) can be used to define the anatomy of an ASD and its influence on the right-sided cardiac chambers and associated anomalies (Fig. 28.13) (46,47). Both CT and MRI also have been used to define the CS type of ASD, which can be particularly challenging to recognize using routine echocardiography (48). Multislice CT has a high spatial and temporal resolution and

multiplanar reconstruction capabilities to characterize ASDs and pulmonary venous anomalies, though at the cost of radiation exposure (49). MRI is being used increasingly in adults since the transthoracic echocardiographic images can be quite limited. MRI has been shown to have a good correlation with TEE in assessing the size and rims of the defect (47). Velocity-encoded, phase-difference MRI measurements of flow in the proximal great vessels has been used to noninvasively measure $Q_p:Q_s$ with results comparable to those obtained by oximetry and indicator dilution techniques (50).

Exercise Testing

Even though most patients with ASD are asymptomatic, their exercise capacity may be decreased. Closure of an ASD may improve exercise capacity in adults who were asymptomatic or mildly symptomatic prior to closure (51). Exercise capacity is uniformly low in patients with ASD and pulmonary hypertension. In cases where the symptoms are discordant with the clinical findings, it can be useful to document the exercise capacity. Exercise testing can be helpful in documenting oxygen saturations during exertion in patients with pulmonary hypertension, though maximal exercise is not recommended in the presence of severe pulmonary hypertension (52).

Natural History of ASDs

While secundum ASDs can spontaneously close over time, other types of ASDs do not. In a report on the natural history of unrepaired ASD, Campbell (53) noted that the mean age of death was 37.5 ± 4.5 years with 75% dying by 50 years and 90% dying by 60 years of age. This was in the era prior to echocardiography where reports regarding outcome of ASDs obviously were skewed toward clinically recognizable defects. Since the advent of echocardiography, it is possible to report data from serial echocardiographic evaluations estimating the change in the size of the defect and the rate of spontaneous closure (54–56). In general, most defects <5 mm that were recognized during infancy are likely

to spontaneously close, while those larger than 8 to 10 mm are unlikely to do so.

In a report of 30 children with secundum ASDs (mean age at diagnosis 1.3 years) that were considered hemodynamically insignificant during infancy, Brassard et al. (57) noted that 17 children had spontaneous closure of the defect at a mean age of 8.4 years. In seven asymptomatic patients, the defect size was 1 to 6 mm at a mean follow-up of 13.2 years. In the remaining six patients, the defect had become larger and closure was performed since the patients were symptomatic or the defect was determined to be hemodynamically significant (57). Radzik et al. (58) evaluated the predictive factors for spontaneous closure of ASDs diagnosed in infants <3 months. They reported that the frequency and timing of closure were inversely related to the diameter of the ASD. At a mean follow-up of about 14 months, spontaneous closure occurred in all the defects that were <3 mm at diagnosis, in 87% of defects that were 3 to 5 mm, in 80% of defects that were 5 to 8 mm, and in none of the defects that were ≥ 8 mm. In a longitudinal study of 200 children with isolated secundum ASDs diagnosed at a median age of 5 months, Hanslik et al. (59) reported spontaneous closure in 34% and a decrease in size to ≤ 3 mm in another 28%. ASD diameter and age at diagnosis were noted to be independent predictors of spontaneous closure or regression to ≤ 3 mm defect size. None of the ASDs >10 mm at diagnosis closed spontaneously (59). In contrast to the above studies, a study by McMahon et al. (60) of 104 patients with isolated secundum ASDs reported that the diameter of ASDs increased in 65% of their cohort, with a >50% increase in 30% of their patients. Spontaneous closure occurred in only 4%, and 12% reached a size of ≥ 20 mm. The mean age at diagnosis in this study was much older (4.5 years, range 0.1 to 71 years) than in the previously mentioned studies, and the mean interval between echocardiograms was 3.1 years (0.7 to 8.1 years), which may contribute to the differences reported in the natural history of secundum ASDs (60).

Pulmonary vascular obstructive disease may develop in patients with large left-to-right shunts during adulthood, though it occurs much later with ASDs compared to high-pressure left-to-right shunts such as ventricular septal defects or patent ductus arteriosus. According to Craig and Selzer (3), young adults with ASD have about a 14% chance of developing progressive pulmonary hypertension. Eventually, when there is reversal of the left-to-right shunt, these patients become progressively cyanotic and symptomatic. They eventually die of cardiac failure or pulmonary artery thrombosis (3). Their pulmonary vascular disease usually is progressive and becomes irreversible. Acute response to vasodilators during cardiac catheterization is helpful to determine reversibility, though some cases may still fall into an indeterminate zone where it is difficult to differentiate between a reversible and an irreversible state. In patients with advanced pulmonary vascular disease, closure of the ASD can result in further deterioration of the patient and decreased survival compared to patients with unrepaired ASDs (61). In most of these patients there is right ventricular failure, and the right-to-left shunt across the ASD provides increased cardiac output albeit at the cost of cyanosis.

Chronic volume overload, elevated pulmonary artery pressures, ventricular dysfunction, and AV valve regurgitation can contribute to atrial stretching, which in turn predisposes to atrial arrhythmias. Late in the natural history of ASDs, atrial arrhythmias in the form of atrial fibrillation, flutter, or less commonly, paroxysmal supraventricular tachycardia contribute to morbidity and mortality.

Management

Most children with an ASD are asymptomatic. In rare cases when they are symptomatic, anticongestive therapy with diuretics may be indicated until closure is accomplished. Closure

of an ASD is indicated if there is a large shunt, that is, $Q_p:Q_s \geq 1.5$. Other indicators of a large shunt include a diastolic flow rumble in the tricuspid area, ECG evidence of right ventricular hypertrophy, chest x-ray evidence of cardiomegaly or increased pulmonary vascular markings, or echocardiographic evidence of right ventricular enlargement and/or paradoxical septal motion (62). In asymptomatic patients with a large shunt, elective closure between 2 and 5 years of age is recommended (62). Even though most children with large defects may be asymptomatic, elective closure is recommended to prevent long-term complications such as atrial arrhythmias, paradoxical embolism, pulmonary hypertension, severe right ventricular dilation and dysfunction with overt symptoms of congestive heart failure, and hemodynamically significant mitral and tricuspid insufficiency. If large ASDs are identified later in life, it is important to have evidence of pulmonary vascular reactivity and a net left-to-right shunt prior to considering closure. Those with irreversible pulmonary hypertension are not candidates for ASD closure and warrant medical therapy for treatment of pulmonary hypertension.

Closure of small defects without any right-sided cardiac enlargement is controversial. While these patients may remain asymptomatic well into their fourth and fifth decades of life, there is concern about increase of the left-to-right shunt at an older age due to reduced left ventricular compliance as a result of CAD, systemic hypertension, or valvular disease (52). Routine follow-up of these patients during adulthood should include assessment for atrial arrhythmias and paradoxical embolic events and an echocardiogram every 2 to 3 years to evaluate right atrial and ventricular size and pressures (52).

Although closure of secundum ASDs can be performed with percutaneous devices or surgically, surgical closure is the only option for sinus venosus, CS, and primum ASDs. ASDs with multiple fenestrations and atrial septal aneurysm (ASA) require careful evaluation before proceeding with device closure.

Secundum ASDs

Surgical Closure: Surgical closure of an ASD was first performed by Murray in 1948 using an external suture technique without directly visualizing the defect. With development of the pump oxygenator, in 1953 Gibbon performed closure of ASD using the open technique that allowed complete visualization of the defect. For small to moderate ASDs direct suture closure can be accomplished. If the ASD is too large to allow direct suture closure, patch closure is performed. Use of autologous pericardial patch has eliminated the need to use prosthetic material, thereby theoretically, minimizing the risks of thromboembolism and endocarditis. In adult patients with atrial arrhythmias, a concomitant Maze procedure can be performed. Conventionally, median sternotomy approach has been used for surgical repair of ASD. More recently, partial

lower sternotomy has been used particularly in children below 3 years of age (63,64).

Surgical mortality and morbidity for secundum ASDs with normal pulmonary vascular resistance are negligible. The majority of patients who had closure of secundum ASDs during childhood have had an uncomplicated course with a normal cardiac rhythm and exercise capacity. Rarely, there may be inadvertent attachment of the eustachian valve to the atrial septum, thereby diverting blood from inferior vena cava to the left atrium and causing a right-to-left shunt, necessitating surgical reintervention.

The long-term outcome following surgical repair of ASD primarily depends on the age at surgery and pulmonary artery pressures prior to surgery. Several investigators have reported the outcome in patients with pulmonary hypertension who have undergone surgical closure of ASD. In 1960, Rahimtoola et al. (65) reported that the outcome in those who had a peak pulmonary artery pressure of more than 60 mm Hg is poor. In 1973, Dave et al. (66) reported that surgical outcome is adversely affected when the mean pulmonary artery pressure was more than 40 mm Hg. In 1987, Steele et al. (25) reported that in patients with pulmonary hypertension, total pulmonary resistance, pulmonary arteriolar resistance, pulmonary-to-systemic resistance ratio, and systemic and pulmonary arterial oxygen saturation were all predictors of surgical outcome, with total pulmonary resistance being the best one. In 1990, Murphy et al. reported the long-term postoperative outcomes of 123 patients at Mayo Clinic between 1956 and 1960 who had surgical repair of secundum or sinus venosus ASDs. The overall 30-year actuarial survival rate among survivors of the perioperative period was 74%, compared to 85% among age- and sex-matched controls (67). The late survival in patients undergoing surgery below 24 years of age was similar to that of the control population. However, survival is significantly decreased in those repaired between 25 and 41 years when compared to the controls (84% and 91%, respectively). There was a further decline in late survival in those repaired after 41 years of age to 40% versus 59% in controls (67). Independent predictors for long-term survival were younger ages at operation and lower preoperative pulmonary artery systolic pressures (67). Late repair was associated with significant morbidity including atrial fibrillation, stroke, and cardiac failure.

Device Closure

Transcatheter device closure of secundum ASDs has significantly altered the management of ASDs. The first transcatheter device closure was reported by King et al. (68) in 1976. Following that, several modifications in devices as well as delivery systems have been made. Various devices such as Amplatzer septal occluder, CardioSEAL, Gore HELEX septal occluder,

Figure 28.14. Various devices used for transcatheter closure of ASD. A: Amplatzer septal occluder (Illustration courtesy of AGA Medical Corp.). B: Gore Helix septal occluder (Illustration courtesy of W.L. Gore & Associates, Inc). C: CardioSEAL device. D: BioSTAR device. (Illustrations C and D courtesy of NMT Medical, Inc.)

Clamshell occluder, Sideris Buttoned device, Das-Angel Wings occlusion device, and BioSTAR are now available (Fig. 28.14). The Amplatzer septal occluder is currently the most widely used device. Some of the advantages of this device include relatively easy deployment, easy retrievability (until released from the delivery system), ability to close large defects, and the relatively larger left atrial disc to close additional atrial fenestrations.

While device closure has proven to be technically safe and feasible and has the obvious advantage of being a nonsurgical technique, it is not free of complications. These complications include fracture or embolization of the device, device malalignment, residual shunts, device thrombosis, and impingement of adjacent structures such as valves, SVC, CS, pulmonary veins, or aorta (69–71). Also, long-term problems such as late erosion of the atrial wall or aorta, inaccessibility of the left atrium if needed, and artifact during MRI can be encountered (72). A partially biodegradable device (BioSTAR) made of collagen discs and metallic arm and rings has been developed to overcome some of these problems. This device has been used in Europe since 2006 for PFO and ASD closure (73). The closure rates are comparable to the Amplatzer device with very little foreign material left over at 6 months' follow-up (74). A fully absorbable transcatheter device (BioTREK) is currently undergoing experimental trials.

In the current era of ASD device closure, several studies have evaluated outcomes of ASD closure using this technique in patients with pulmonary hypertension. In 2008, Balint et al. (75) reported the outcome of device closure of ASD with moderate or severe pulmonary arterial hypertension. They noted that at a mean follow-up of 31 months, although there was a decrease in the mean right ventricular systolic pressures as determined by echocardiography, it normalized in only 44%, while 15% had persistence of severe pulmonary hypertension. In 2009, Yong et al. (76) reported a longitudinal study evaluating pulmonary hypertension in 215 adults with attempted device closure of ASDs. Independent predictors of moderate or severe pulmonary hypertension were older age, larger ASD, female sex, and presence of at least moderate tricuspid regurgitation (76). Among patients with moderate or severe pulmonary hypertension, independent predictors of normalization of pulmonary pressure were lower baseline pulmonary artery pressure and no more than mild tricuspid regurgitation (76). In a study of 236 adults who had device closure of ASD at a mean age of 49 ± 18 years, Humenberger et al. (77) found that ASD closure at any age was followed by improvement in symptoms and decrease in pulmonary artery pressures and right ventricular size, but the best outcome was in patients with less functional impairment and lower baseline pulmonary artery pressures. These studies indicate that, similar to surgical closure of ASDs, the outcome following device closure is influenced by age at closure and the presence of pulmonary hypertension.

Sinus Venosus ASD

In the rare case where the sinus venosus ASD is not associated with anomalous pulmonary venous return, an autologous pericardial patch closure of the ASD is performed. However, in more than 90% of cases, anomalous pulmonary venous return to the SVC is present. In such cases, surgical correction involves closure of ASD and redirection of anomalous pulmonary veins into the left atrium. While the surgery for superior, posterior, and inferior sinus venous ASD with anomalous veins draining directly into the right atrium is associated with minimal complications, that for anomalous pulmonary veins connected to SVC is complex and can be associated with long-term complications such as obstruction of the pulmonary vein orifice, SVC stenosis, sinus node dysfunction, and

atrial arrhythmias, including atrial flutter or atrial fibrillation depending on the surgical technique used. In the intracaval baffle technique the anomalous pulmonary venous return is redirected through the sinus venosus defect by baffling these structures with a pericardial or synthetic patch with or without performing a patch cavoplasty as needed (78). The transcaval technique uses a lateral incision in the SVC and a single-patch closure of the ASD along with baffling of anomalous pulmonary veins into the left atrium (79). When the right pulmonary venous insertion into the SVC is high (more than 2 cm above the atriocaval junction), the Warden procedure is used, in which the SVC is transected above the site of the anomalous pulmonary veins and connected to the right atrial appendage. The cardiac end of the SVC along with the anomalous pulmonary venous flow is baffled into the left atrium with a patch (80).

Coronary Sinus ASD

In a partially unroofed CS defect, repair can be performed using a roofing procedure (81). If there is redundant tissue, primary closure of the defect can be performed. If that is not feasible, a roof can be created using a pericardial patch.

Most cases of CS ASD are associated with a left SVC which is dealt with on its own merits. If the left SVC is small and there is a bridging vein, it can be ligated. If it is large and is the only source of systemic venous drainage from the head and upper extremities, an intraatrial baffle can be performed.

Management Issues During Follow-Up

Patients who had surgical closure of ASD during childhood have an excellent outcome. In general, they have decrease in or resolution of preoperative symptoms, an increase in exercise capacity, and are free of significant cardiac rhythm abnormalities. However, the outcome in those who had surgery during adulthood is significantly different due to pulmonary hypertension, atrial arrhythmias, and cardiac failure. Device closure is also associated with early and long-term complications as mentioned above which warrant long-term surveillance. Specific issues that need attention during follow-up are discussed below.

Postpericardiotomy Syndrome

During the first few weeks postoperatively, patients may present with fever, chest pain, abdominal pain, emesis, and fatigue. These symptoms should alert one to the diagnosis of postpericardiotomy syndrome, and an echocardiogram should be performed to exclude pericardial effusion and cardiac tamponade.

Pulmonary Hypertension

It is well established that the outcome of patients with repaired or unrepaired ASD and pulmonary hypertension is not favorable compared to those with normal pulmonary artery pressure. Despite closure of the defect, pulmonary vascular disease may progress in some patients. Therefore, periodic surveillance along with serial Doppler echocardiograms is recommended to estimate pulmonary artery pressures. Medical therapy using pulmonary vasodilators should be instituted if indicated.

Atrial Arrhythmias

Atrial fibrillation and flutter are uncommon in patients with ASD before the age of 40 years with a prevalence of <1% (82). Beyond 40 years of age, the prevalence increases significantly compared to that of the general population: 15% and 61% at 40 to 60 years and beyond 60 years, respectively (82). Patients

with atrial arrhythmias also are more likely to have higher pulmonary artery pressures and worse functional class (83). Patients older than 40 years at the time of ASD closure are more likely to have new-onset atrial arrhythmias. Those with atrial arrhythmias before and soon after ASD closure are more likely to have persistent arrhythmias (83). In patients predisposed to atrial arrhythmias, periodic follow-up with ECG and Holter monitoring is recommended. Atrial arrhythmias should be appropriately treated to restore and maintain sinus rhythm. If sinus rhythm cannot be restored with medical or interventional means, then rate control and anticoagulation are recommended (52).

Right Atrial and Ventricular Size and Function

Following ASD closure, there is regression of right atrial and ventricular size in the majority of patients, irrespective of the technique used for closure (46,84). Most of the regression occurs within the first year following closure (85). While significant changes in the right atrial size may not be observed acutely, that too decreases over time (86). Regression in right heart size is less in patients repaired at an older age and in those with pulmonary hypertension. Right ventricular systolic function is normal to hyperdynamic in those with unrepaired ASDs, but chronic volume overload can result in reduced right ventricular systolic and diastolic dysfunction in adults, which may or may not improve following closure of the defect.

Left Ventricular Function

Although earlier reports indicated that left ventricular function was normal in patients with ASD, there is now evidence that both systolic and diastolic function can be influenced adversely by severe chronic right ventricular volume overload (87–89). Therefore, monitoring of both right and left ventricular function during follow-up is advisable.

Mitral Regurgitation

Patients with ASD may develop mitral valve prolapse and insufficiency, presumably from leftward shifting of the ventricular septum due to an enlarged right ventricle (90). This may persist after successful closure of the defect (90,91). While the etiology of mitral regurgitation has been ascribed to mechanical ventricular dysfunction, the valve itself often is noted to be morphologically abnormal with myxomatous changes and prolapse (92).

Bacterial Endocarditis

Patients with isolated ASDs are not predisposed to endocarditis unless there is an associated valvular lesion such as cleft mitral valve with mitral valve regurgitation. There are rare reports of bacterial endocarditis following uncomplicated surgical or device closure of ASD. Endothelialization of prosthetic material or devices usually occurs within the first 6 months after the procedure. Therefore, antibiotic prophylaxis is recommended for the first 6 months following such a procedure and is then discontinued (93).

ASD in Adults

ASD is the most common congenital heart disease in adults accounting for up to 30% of congenital heart defects in this age-group. Patients with ASD may survive into adulthood without being diagnosed. Although many come to attention due to abnormal physical findings, chest x-ray, or ECG, some may present with a cerebrovascular event due to paradoxical embolism or signs and symptoms related to cardiac failure,

arrhythmias, or pulmonary hypertension. Dyspnea on exertion is the most prevailing symptom present in symptomatic adults with ASD. Other symptoms include fatigue, palpitations, and rarely, chest pain (3). The development of these symptoms can be attributed to multiple factors. In older patients, left ventricular compliance may be reduced due to systemic hypertension or CAD, which in turn increases the left-to-right shunt across the ASD. Chronic right ventricular volume overload ultimately results in right ventricular failure and progressive tricuspid valve insufficiency. Survival into adulthood is quite common with infrequent deaths during the first two decades of life. Symptoms of progressive pulmonary hypertension can begin in the third decade. The mortality rate is significant after the fourth decade, around 6% per year (53).

Adults who had surgical repair of secundum ASDs during childhood are usually symptom free, but rarely can have atrial arrhythmias and sick sinus syndrome (94). When surgery is performed in adults, the outcome primarily depends on the age at repair and the pulmonary artery pressures. Konstantinides et al. (95) compared outcomes of 179 patients ≥ 40 years with secundum ASD who were treated either medically or surgically. The 10-year survival in the medically managed group was 84% compared to 95% in surgically managed group. The functional status of one-third of the medically managed patients deteriorated, but improved in those who had surgical repair, though the incidence of atrial arrhythmias and cerebrovascular events was similar in both groups (95). Horvath et al. (96) reported early and long-term follow-up of surgical repair of secundum and sinus venosus ASDs in 166 adults repaired at Brigham and Women's Hospital at a mean age of 44 years. The 5- and 10-year survival rates were 98% and 94%, respectively. There were two operative deaths and six late deaths. Those with a systolic pulmonary artery pressure of >30 mm Hg had significantly higher late mortality. St John Sutton et al. (97) reported patients who had surgical closure of ASD between 60 and 78 years. There was improved survival in patients discharged from the hospital following surgery compared to age- and sex-matched medically treated controls. In this study, the majority of patients showed symptomatic improvement irrespective of preoperative pulmonary vascular resistance and functional class (97). Based on these studies and several others in the literature, there is general agreement that symptomatic adult patients improve after closure of ASD; the only contraindication for closure is severe pulmonary hypertension. There is some controversy over management of asymptomatic adults, but closure can be performed with minimal risk with the advantage of reducing overload of right ventricle and progression of tricuspid insufficiency and in many cases reducing progression of pulmonary hypertension. Moreover, there is improvement in functional capacity even in asymptomatic patients following ASD closure (51). Given the low mortality and morbidity associated with closure of ASD within the first two decades of life, these patients have no cardiac restrictions and can have less frequent follow-up provided there is no cardiac rhythm or hemodynamic concerns. Patients repaired in their third decade and beyond require regular surveillance for atrial arrhythmias, cardiac failure, stroke, and pulmonary vascular disease (52,98).

In general, pregnancy in patients with ASD is well tolerated as the increase in the left-to-right shunt across the atrial septum is balanced by the decrease in peripheral vascular resistance. Paradoxical embolism may occasionally occur unrelated to the size of the ASD. Pregnancy is not recommended in patients with ASD and severe pulmonary artery hypertension due to very high maternal and fetal mortalities (52). Such patients may develop arrhythmias, ventricular dysfunction, and progressive pulmonary hypertension during pregnancy.

Atrial Septal Aneurysm

An ASA is a saccular deformity of the atrial septum with a reported prevalence of 0.22% to 1.9% (99,100). Although in most cases the aneurysm is limited to the region of the fossa ovalis, it occasionally can involve the entire septum (Fig. 28.15D). ASA may protrude into the left or the right atrium or have a bidirectional excursion. Various classifications of ASA based upon its excursion have been proposed (99,100). Hanley et al. (99) suggested diagnostic criteria for ASA based on transthoracic echocardiograms that include (a) protrusion of the aneurysm at least 15 mm beyond the plane of the atrial septum or when the atrial septum shows a phasic excursion of ≥ 15 mm during the cardiorespiratory cycle and (b) the base amplitude (width) of the aneurysm ≥ 15 mm. Although ASAs may occur in isolation, they commonly are associated with congenital or acquired heart disease. The most commonly associated cardiac lesion is ASD, though other lesions such as ventricular septal defects, pulmonary stenosis, patent ductus arteriosus, coarctation, and interrupted aortic arch can occur (101). ASAs also have been associated with atrial arrhythmias, AV valve prolapse, and systemic and pulmonary embolism (99). The association of ASA with cerebrovascular events, in particular cryptogenic strokes has been reported. The coexistence of a PFO with an ASA further increases the risk of stroke. The potential source of embolization in these cases could be a primary thrombus in the aneurysm or paradoxical embolization through interatrial

shunting (102,103). TEE provides superior images for morphologic characterization of ASA. It also is helpful in defining interatrial shunting and the presence of multiple fenestrations and thrombi within the aneurysm (102,104).

Management of patients with ASA and stroke includes medical therapy with aspirin or warfarin or closure by surgical or transcatheter technique (105).

Patent Foramen Ovale

A PFO is a normal interatrial communication present in fetal life that persists in many adults (Fig. 28.15). Based on transesophageal echocardiography, it is present in up to 24% of healthy adults (106). A Mayo Clinic study based on 965 autopsy specimens of human hearts reported the incidence and size of the PFO during the first 10 decades of life (107). While the overall incidence was 27.3%, it progressively declined with increasing age from 34.3% during the first three decades of life to 25.4% during the fourth through eighth decades and to 20.2% during the 9th and 10th decades (107). Furthermore, the PFO size increased from a mean of 3.4 mm in the first decade to a mean of 5.8 mm in the 10th decade, likely due to stretching of the fossa ovalis over time. The incidence and size of PFO were reported to be similar in males and females (107).

In the current era, transcatheter closure of PFOs is performed using a wide variety of devices such as Amplatzer, CardioSEAL-STARflex, Helex occluder, and BioSTAR, a new

Figure 28.15. Patent foramen ovale. A: Right atrial view. B: Left atrial view. A white probe is seen between the limbus and valve (V) of the fossa ovalis and enters the left atrium (LA) through the ostium secundum (white arrow). C: Right atrial view. Atrial dilation has resulted in a valvular-incompetent PFO, that is, an acquired ASD (asterisk). D: Atrial septal aneurysm. Four-chamber view showing aneurysm of the fossa ovalis (arrows) bulging toward the right. LAA, left atrial appendage; VS, ventricular septum. (See Fig. 28.2 for other abbreviations.)

bioabsorbable implant (108,109). While the safety and efficacy of these devices has been reported in many studies, complications are similar to those with the devices used for ASD closure and include device embolization, hemopericardium, device thrombosis, residual shunts, and paroxysmal atrial fibrillation (108).

PFO has been associated with cryptogenic strokes, transient ischemic attacks, and migraine headaches (110). Systemic, noncerebral paradoxical embolism also rarely can occur in the form of myocardial infarction, renal infarction, or limb ischemia (111). The prevalence of PFO has been noted to be higher in patients with cerebrovascular events than in those without cerebral vascular events ranging from 40% to 70%. Therefore, a potential etiologic role has been suggested. These patients have been treated with antithrombotic drugs like warfarin and aspirin, or closure has been performed to prevent future events (105,112,113). The recurrence of these events is not completely eliminated following surgical or transcatheter closure of PFO (113). Similar to studies in patients with stroke, some studies have reported relief of migraine with aura following closure of PFO (114–116). However, a recent population-based study of 1,100 stroke-free patients with self-reported migraines did not find any significant associations between PFO and migraine (117). Direct documentation of paradoxical embolization through the PFO resulting in cerebrovascular events obviously is challenging. Hence, the role of closure of PFO in such patients remains controversial. In the current era of device closure, there has been a dramatic increase in the rate of PFO closure in these patients in light of some observational studies reporting reduced incidence of recurrence. However, there are no randomized control trials as yet to prove the benefit of closing PFOs (105,118,119).

INTRODUCTION AND NOMENCLATURE

Atrioventricular septal defects (AVSDs) are a group of anomalies that share a defect of the atrioventricular (AV) septum and abnormalities of the AV valves. The terms “AV canal defects” or “endocardial cushion defects” also describe these lesions but, for the purposes of this chapter, the term *atrioventricular septal defect* is used. These lesions are divided into partial and complete forms. In partial AVSD, a primum atrial septal defect (ASD) always is present and there are two distinct, but focally contiguous, right and left AV valve annuli. The left AV valve invariably is cleft. The complete form also includes a primum ASD, but it is contiguous with an inlet ventricular septal defect (VSD), and the common AV valve has a single annulus. Similarly, the clinical manifestations and management of these patients depend on the extent and severity of the lesions present.

Several classifications have been used to describe AVSDs. *Transitional AVSD* is a subtype of partial AVSD. This term is used when a partial AVSD also has a *small* inlet VSD that is partially occluded by dense chordal attachments to the ventricular septum. *Intermediate AVSD* is a subtype of complete AVSD that has distinct right and left AV valve orifices despite having only one common annulus. These separate orifices are referred to as right and left AV valve orifices rather than tricuspid and mitral. This also is true when describing the valves after repair of complete AVSD. The VSD in intermediate AVSD is large similar to other forms of complete AVSD. Unfortunately, the terms “transitional” and “intermediate” have been confused and are used synonymously in the literature. Because of the conflicting and confusing terminology of these subtypes, the clinician, echocardiographer, and surgeon should communicate by simply describing AV valve morphology, cardiac chamber sizes, and magnitude of shunting observed. Complete and intermediate AVSDs have the physiology and clinical features of a combined ASD and VSD, whereas partial and transitional AVSDs have the clinical picture of a large ASD (Fig. 29.1). Anatomic features shared by all forms of AVSD are summarized in Table 29.1.

Surgical repair of AVSDs has been one of the great successes of the last several decades of congenital cardiac surgery. Recently, the Pediatric Heart Network (PHN) reported AVSD outcome data from seven North American centers demonstrating an overall operative mortality of 3% (1,2). Long-term survival has been excellent. Cumulative 20-year survival of 95% has been reported (3). This success has been tempered by the relatively large number of patients (~25%) who await reoperation, most commonly because of progressive left AV valve regurgitation or for relief of left ventricular outflow tract (LVOT) obstruction. Unfortunately, the prevalence of postoperative left AV valve regurgitation has remained the most common sequel of repair for decades. The PHN study found that 26% of patients had more than moderate left AV regurgitation 6 months after “repair” (1,2).

DEMOGRAPHICS

AVSDs account for 4% to 5% of congenital heart defects and the estimated occurrence is 0.19 in 1,000 live births (4,5). In a large fetal echocardiography experience, AVSD was the most common anomaly detected, constituting 18% of abnormal fetal hearts (6). In utero diagnosis of an AVSD is made on routine fetal four-chamber imaging. Gender distribution is approximately equal or may show a slight female preponderance (4).

About 40% to 45% of children with Down syndrome have congenital heart disease, and among these, approximately 45% have an AVSD. In more than 75% of patients with Down syndrome, it is the complete form of AVSD (7). Conversely, approximately 50% of patients with AVSD have Down syndrome. Race and ethnicity may factor into prevalence of AVSD in patients with Down syndrome. Patients of Black African ancestry with Down syndrome have AVSD more commonly than do whites. Familial occurrence of AVSD is rare. Complete AVSDs also occur in patients with heterotaxy syndromes (more common with asplenia than with polysplenia). Common atrium has been associated with Ellis-van Creveld and heterotaxy syndromes (8–11).

EMBRYOGENESIS

The etiology of AVSDs has traditionally been considered as faulty development of the AV endocardial cushions. However, recent studies have illustrated additional pathways involving the “dorsal mesenchymal protrusion” that may act alone or in concert with development of the endocardial cushions to create AVSDs (12). In partial AVSDs, incomplete fusion of the superior and inferior endocardial cushions results in a cleft in the midportion of the left AV valve anterior leaflet often associated with regurgitation. In contrast, complete AVSD is associated with lack of fusion between the superior and inferior cushions and, consequently, with the formation of separate anterior and posterior bridging leaflets along the subjacent ventricular septum (Fig. 29.2).

Failure of the endocardial cushions to fuse creates a defect in the AV septum. The primum atrial septal component of this defect usually is large. This results in downward displacement of the anterior left AV valve leaflet to the level of the septal right AV valve leaflet (13). In AVSDs, the AV valves have the same septal insertion level in contrast to the leaflet arrangement in the normal heart (Fig. 29.3). The distance from the cardiac crux to the left ventricular apex is foreshortened, and the distance from the apex to the aortic valve is increased. This is in contrast to the normal heart, in which the two distances are roughly equal (Fig. 29.4). In AVSDs, the disproportion between the two distances causes anterior displacement of

Figure 29.1. Summary of AVSD. Anatomic and physiologic similarities between the different forms of AVSD are illustrated. Complete AVSDs have one annulus with large interatrial and interventricular communications. Intermediate defects (one annulus, two orifices) are a subtype of complete AVSD and have a large ventricular septal defect (VSD). Complete AVSDs have physiology of VSDs and ASDs. In contrast, partial AVSDs have physiology of ASDs. Transitional defects are a form of partial AVSD in which a *small* inlet VSD is present. Partial AVSD and the intermediate form of complete AVSD share a similar anatomic feature: A tongue of tissue divides the common atrioventricular valve into distinct right and left orifices. LA, left atrium; LPV, left pulmonary vein; LV, left ventricle; RA, right atrium; RPV, right pulmonary vein; RV, right ventricle. (With permission of Patrick O’Leary, MD.)

the LVOT resulting in elongation and narrowing of the LVOT producing the characteristic “goose-neck” deformity. After surgical repair of the defect, progressive subaortic stenosis still may develop (14).

Since the dextrodorsal conus cushion contributes to the development of the right AV valve and the outflow tracts lie adjacent to their respective inflow tracts, AVSDs may be associated with conotruncal anomalies, such as tetralogy of Fallot and double-outlet right ventricle (RV). In addition, shift of the AV valve orifice may result in connection of the valve primarily to only one ventricle, creating disproportionate or unbalanced ventricles.

PARTIAL ATRIOVENTRICULAR SEPTAL DEFECT

Pathology

In partial AVSD, the right and left AV valve annuli are separate. The most frequent form of partial AVSD consists of a primum ASD and a cleft left AV valve anterior leaflet (Figs. 29.5 and 29.6). Most primum ASDs are large and located anterior and inferior to the fossa ovalis. The defect is bordered by a crescentic rim of atrial septal tissue posterosuperiorly and by AV valve continuity anteroinferiorly. These defects are not amenable to transcatheter device closure because of their proximity to the AV valves.

TABLE 29.1

Anatomic Features Shared by All Forms of AVSD

- AV valve leaflets insert at the same level at the cardiac crux
- Absence of the AV septum
- Unwedged and anterior displacement of the aortic valve
- Elongated LVOT
- Counterclockwise rotation of the LV papillary muscles
- Cleft left AV valve component, directed toward the ventricular septum

The right and left AV valves have the same septal insertion level because the left AV valve annulus is displaced toward the ventricular apex. As a result, the deficient AV septum is associated with an interatrial communication rather than an interventricular or right atrial to left ventricular communication. Nonetheless, the defect imparts a scooped-out appearance to the inlet ventricular septum, and the distance from the left AV valve annulus to the left ventricular apex is less than the distance from the aortic annulus to the apex (Fig. 29.4).

The cleft in the left AV valve anterior leaflet is directed toward the midportion of the ventricular septum, along the anteroinferior rim of the septal defect (Fig. 29.7). In contrast, isolated mitral valve clefts (not associated with AVSD) are directed toward the aortic valve annulus (15). The left AV valve orifice is triangular rather than elliptical (as in a normal heart) and resembles a mirror-image tricuspid valve orifice. The cleft left AV valve usually is regurgitant and, with time, becomes thickened and exhibits histologic alterations that resemble myxomatous mitral valve prolapse.

The most common associated anomalies with partial AVSD are a secundum ASD, patent ductus arteriosus (PDA), and a persistent left superior vena cava connecting to the coronary sinus (1). Less frequently, pulmonary stenosis, tricuspid stenosis or atresia, cor triatriatum, coarctation of the aorta, membranous VSD, pulmonary venous anomalies, and hypoplastic right or left ventricle (LV) have been reported (16–18).

Clinical Manifestations

Although patients with partial AVSD may be asymptomatic until adulthood, symptoms of excess pulmonary blood flow typically occur in childhood. Tachypnea and poor weight gain occur most commonly when the defect is associated with moderate or severe left AV valve regurgitation or with other hemodynamically significant cardiac anomalies. Patients with primum ASDs usually have earlier and more severe symptoms, including growth failure, than patients with secundum ASDs.

An uncomplicated primum ASD often is discovered in young children when echocardiography is performed to investigate a murmur. The murmur has typical systolic ejection qualities and is best heard over the upper left sternal border with radiation to the lung fields. The murmur is caused by turbulent flow across the pulmonary valve (not flow through the ASD). The second heart sound is widely split and fixed during respiration. An S1-coincident

Figure 29.2. Diagram of the embryologic development of the AV canal region and the spectrum of AVSD, including partial, transitional, complete, and intermediate forms. A, anterior leaflet; AB, anterior bridging leaflet; DDCC, dextrodorsal conus cushion; IEC, inferior endocardial cushion; LEC, lateral endocardial cushion; P, posterior leaflet; PB, posterior bridging leaflet; S, septal leaflet; SEC, superior endocardial cushion; L, lateral leaflet.

holosystolic murmur due to left AV valve regurgitation through the cleft may also be heard at the apex. A low-pitched middiastolic murmur heard at the left lower sternal border may be present if the shunt is large or if significant left AV valve regurgitation is present.

Echocardiography

Two-dimensional echocardiography is the primary imaging technique for diagnosing AVSDs (19–21). It is useful particularly for delineating the morphology of the AV valves.

Figure 29.3. AV septum in the normal heart (four-chamber view). The atrioventricular septum (AVS) lies between the RA and the left ventricle (LV) with the interatrial septum (IAS) above and the interventricular septum (IVS) below. The septal tricuspid leaflet (TV—right AV valve) normally inserts at a lower (more apical) level than the anterior mitral leaflet (MV—left AV valve). LA, left atrium; RV, right ventricle. (From Edwards WD. Applied anatomy of the heart. In: Brandenburg RO, Fuster V, Giuliani ER, et al., eds. *Cardiology: Fundamentals and Practice*. Vol. 1. Chicago, IL: Year Book Medical, 1987:47–109, with permission of Mayo Foundation.)

Transesophageal echocardiography (TEE) can provide incremental diagnostic information in larger patients or in patients with associated complex abnormalities.

The internal cardiac crux is the most consistent echocardiographic imaging landmark (19). The apical four-chamber imaging plane clearly allows visualization of the internal crux where the primum ASD is seen as an absence of the lower atrial septum. The size of the primum ASD is made reliably from this imaging position (Fig. 29.8) or from the subcostal four-chamber (frontal) projection. Accurate visualization of the cardiac crux also permits assessment of the AV valves. Several 2-D echocardiographic features are shared by all forms of AVSD: deficiency of a portion of the inlet ventricular septum, inferior displacement of the AV valves, and attachment of a portion of the left AV valve to the septum. The AV valves are displaced toward the ventricles, with the septal portions inserting at the same level onto the crest of the ventricular septum. Therefore, in these defects, the two separate AV valve orifices are equidistant from the cardiac apex.

In the transitional form of partial AVSD, there is aneurysmal replacement of a portion of the inlet ventricular septum (21) (Fig. 29.9A,B). Small shunts may occur through this so-called “tricuspid pouch.” However these dense chordal attachments eventually obstruct flow. Spectral and color flow Doppler hemodynamic assessments are useful to determine the severity of AV valve stenosis or insufficiency and to quantitate right ventricular systolic pressure. Doppler echocardiography often is not useful for evaluating the degree of left AV valve stenosis in the setting of a primum ASD because the ASD will decompress the left atrium (LA).

Other left AV valve abnormalities are typical with both the partial and complete forms of AVSD (Fig. 29.10A). The most common abnormality, a cleft, is best visualized from the parasternal and subcostal short-axis imaging planes. Careful 2-D and color Doppler assessment of the left AV valve cleft needs to be performed since multiple jets of regurgitation may be present. LV to right atrium (RA)-directed left AV valve regurgitation is usually remedied during surgery with successful repair of the cleft and closure of the primum ASD. LV to LA regurgitation may not be completely eliminated with cleft repair and may signify other intrinsic abnormalities with the valve. An important factor that predicts the amount of residual postoperative left AV valve regurgitation is the degree of preoperative regurgitation. Rarely, other abnormalities of the left AV valve occur such as a parachute or a double-orifice valve.

Figure 29.4. Elongate LVOT in AVSD: Because of deficiency of the ventricular component of the AV septum and the “sprung” AV junction, the distance from the LV apex to the posterior left AV valve annulus is 20% to 25% shorter than the distance from the apex to the aortic annulus. Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle. (With permission of Robert H. Anderson, MD.)

Figure 29.5. Top left: Four-chamber anatomic specimen demonstrating a large primum ASD (arrow), severe RA and RV dilation, and connection of both AV valves to the septum at the same level. Top right: Corresponding apical four-chamber diastolic image demonstrating severe RA and RV dilation owing to a large primum ASD (arrow). Bottom left: Color Doppler scan from the apex, demonstrating a large left-to-right shunt crossing the primum ASD in diastole (red flow jet). Bottom right: Systolic color flow Doppler displaying moderate right and left AV valve regurgitation. LA, left atrium.

Figure 29.6. Partial AVSD: AV valve anatomy. **Top left:** Systolic apical four-chamber image demonstrating that both right and left AV valves insert onto the crest of the ventricular septum at the same level. **Top right:** Corresponding diastolic frame showing a large primum ASD. Systolic frames often understate the size of the interatrial communication. There is significant RA and RV enlargement. **Bottom panels:** These are parasternal short-axis scans focused at the valve leaflet level in the left ventricular inflow. The **left panel** demonstrates the cleft in the anterior leaflet of the left AV valve (*asterisk*). The anterior leaflet is made of two separate components that move independently. This creates the diastolic gap in the leaflet (*asterisk*). Color Doppler on the **right panel** shows considerable regurgitation through the cleft. LA, left atrium; LV, left ventricle.

Double-orifice left AV valve occurs in 3% to 5% of AVSDs (22). This abnormality is more common when two distinct right and left AV valve orifices are present. A tongue of tissue may divide the left AV valve into two orifices. The combined effective valve area of a double-orifice valve always is less than the valve area of a single-orifice valve. This predisposes the valve to postoperative stenosis. Standard subcostal and parasternal short-axis views usually demonstrate the double-orifice valve characteristics (Fig. 29.10B,C). However, in the setting of a common AV valve, the diagnosis may be challenging. Double-orifice left AV valve rarely occurs in hearts that do not have AVSD. In contrast to AVSD, in the otherwise normal

heart, double-orifice mitral valves have complete duplication of the valve structure.

In the normal heart, the aortic valve is wedged between the mitral and tricuspid annuli. In AVSD, the aortic valve is displaced or “sprung” anteriorly (Fig. 29.11). This anterior displacement creates an elongate, so-called gooseneck deformity of the LVOT (Fig. 29.12) that predisposes the patient to progressive subaortic obstruction. LVOT obstruction may occur in all subtypes of AVSD. It is more frequent when two distinct AV valve orifices are present rather than when there is a common orifice. But whenever the superior bridging leaflet attaches to the crest of the ventricular septum,

Figure 29.7. Cleft left AV valve: **Left:** In AVSD, the cleft in the anterior leaflet of the left AV valve is typically oriented toward the midportion of the ventricular septum (*arrow*) along the anterior–inferior rim of the septal defect. **Right:** Subcostal sagittal image demonstrating the septal orientation of the cleft. A, anterior; PMS, papillary muscles; RV, right ventricle; S, superior.

Figure 29.8. AVSD and the internal cardiac crux. The internal cardiac crux is best visualized in the apical four-chamber imaging plane. In the normal heart, the anterior leaflet of the mitral insertion is more superiorly fixed than the corresponding tricuspid septal leaflet. In all forms of AVSD, both right and left AV valve components insert at the same level on the crest of the inflow ventricular septum. A cleft in the left AV valve occurs in conjunction with the downward displacement of the anterior leaflet. In partial AVSD, there is a defect in the lower fatty portion of the atrial septum (i.e., within the atrial ventricular septum). In complete AVSD, there is a defect beneath the AV valves in the inflow ventricular septum. In general, these easily recognized anatomic features distinguish normal from partial and complete AVSD. AVC, atrioventricular canal.

Figure 29.9. A: Transesophageal echocardiogram in a four-chamber projection demonstrating a typical primum ASD in a 20-year-old patient with partial AVSD. No VSD is present. B: In contrast to image 9A, this patient has a transitional AVSD. Note the membranous aneurysm in the inflow ventricular septum (arrows). There is a primum ASD; clinically, it presents as a partial AVSD. There can be restrictive VSDs in the inflow aneurysmal membrane. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; VS, ventricular septum.

Figure 29.10. Echocardiographic features of left AV valve anomalies in AVSD. **A:** Cleft left AV valve. The left AV valve has a characteristic break (*arrow*) that represents a cleft in the anterior leaflet. This is a feature of all forms of AVSD. **B:** Double-orifice left AV valve imaged in the subcostal sagittal plane, typically encountered with partial AVSD. Each papillary muscle receives a separate AV valve orifice (*arrows*). The anterolateral valve component is usually cleft. **C:** Parasternal short-axis image of a double-orifice left AV valve with a cleft (*arrow*) in the anterolateral component. LV, left ventricle; RV, right ventricle; VS, ventricular septum.

creating two orifices, this further elongates and narrows the LVOT. In addition, discrete subaortic fibromuscular ridges, septal hypertrophy, abnormal left AV valve chordal attachments, and abnormally oriented papillary muscles can further exacerbate the subaortic narrowing. LVOT obstruction may be subtle and therefore not appreciated during the preoperative echocardiographic assessment. LVOT obstruction may

develop de novo after initial repair of AVSD (23) (Fig. 29.13). The LVOT obstruction often is progressive. Even after primary repair of partial AVSD in adulthood, de novo LVOT obstruction may occur. The Mayo Clinic has reported the case of a 58-year-old woman who had reoperation for LVOT obstruction after primary repair of partial AVSD at age 45 years (24).

Figure 29.11. Sprung aortic valve: **Left:** Normal heart pathologic specimen cut in short axis at the base demonstrating where the AV junction has a figure-of-8 configuration. **Right:** Similar projection in an AVSD heart where the AV junction is “sprung.” The aortic valve is anterior of the AV junction instead of being wedged between the AV valve annuli.

Figure 29.12. Because of the anterior displacement of the LVOT in AVSD, the elongate LVOT has been described as a “goose neck” with echocardiographic and angiographic imaging. **Left:** subcostal frontal view of the LVOT. **Middle:** pediatric and adult goose necks in Minnesota. **Right:** Prograde LV angiograph demonstrating elongate LVOT.

Figure 29.13. **A:** LVOT obstruction: systolic (left) and diastolic (right) echocardiograms demonstrating LVOT obstruction in a 17-year-old who had repair of a partial AVSD at age 15 months. LVOT obstruction (arrow) is usually progressive and may be undetected at time of initial repair. **B:** LVOT obstruction: parasternal long-axis projection demonstrating left AV valve attachments (arrow) to the septum in a patient after repair of partial AVSD. 10% to 15% of patients with AVSD require reoperation to relieve LVOT obstruction. Progressive LVOT obstruction is more common in partial than in complete AVSD. Mechanisms of LVOT obstruction include attachments of superior bridging leaflet to ventricular septum, extension of the anterolateral papillary muscle into the LVOT, discrete fibrous subaortic stenosis, tissue from an aneurysm of the membranous septum bowing into the LVOT.

Detailed and comprehensive echocardiographic assessment is required to evaluate associated lesions and determine their significance. Tetralogy of Fallot, double-outlet RV, and pulmonary valve atresia are associated with all forms of AVSDs but are less frequent with partial AVSD. In contrast, AV valve abnormalities and left ventricular hypoplasia are more frequent in two-orifice AV connections. Coarctation of the aorta occurs with equal frequency in partial and complete AVSD.

Radiography

Typically, chest radiography demonstrates cardiomegaly and prominent pulmonary vascular markings. Because the jet of mitral regurgitation often is directed into the RA, right atrial enlargement rather than left atrial enlargement may be apparent.

Electrocardiography and Electrophysiology

The position of the AVSD dictates the position of the AV conduction tissues. Accordingly, the AV node is displaced posteriorly, near the orifice of the coronary sinus, and the His bundle is displaced inferiorly, along the inferior rim of the septal defect. The displacement of the AV conduction tissues, in conjunction with loss of ventricular septal myocardium, results in left axis deviation in the frontal plane QRS.

Sinus rhythm is present in most patients with a primum ASD. Prolongation of the P-R interval, in relation to patient age and heart rate, is seen in approximately 25% of patients. It is due primarily to increased conduction time from the high RA to the low septal RA (25). P-wave changes indicating right atrial, left atrial, or biatrial enlargement are seen in approximately half of patients. The mean QRS axis in the frontal plane ranges from -30 degrees to -120 degrees, with most axes between -30 degrees and -90 degrees. Anatomic and electrophysiologic studies show that this abnormal vectorcardiographic pattern is associated with a specific anomaly of the conduction system (26). Right ventricular volume overload results in right ventricular hypertrophy and some variation of the rsR' or RSR' pattern in the right precordial leads in 80% of patients; 10% of patients have a qR pattern. Patients with significant left AV valve regurgitation may have evidence of left ventricular hypertrophy.

Except for prolonged intra-atrial conduction time, other intracardiac electrophysiologic measurements usually are normal, including sinus node function, AV node function, His-Purkinje conduction time, and refractory periods (25).

Cardiac Catheterization and Angiography

Cardiac catheterization and angiography rarely are necessary for diagnosis or management of patients with a partial AVSD. Current echocardiographic techniques accurately define the anatomy and physiology of this lesion. In an older patient, cardiac catheterization may have a role in assessing the degree of pulmonary vascular obstructive disease or coronary artery disease.

A large left-to-right shunt can be demonstrated at atrial level by a higher oxygen saturation sampled from the RA compared with the blood in the inferior and superior vena cavae. Because of the anatomic position of the ASD, blood samples taken from the inflow portion of the RV may have elevated oxygen saturation. The calculated left-to-right shunt often exceeds 50%. In most patients, right ventricular pressure is $<60\%$ of systemic pressure. A significant increase in

calculated pulmonary vascular resistance is unusual in infants. Left ventricular angiography will demonstrate the elongate gooseneck deformation of the LVOT (Fig. 29.12).

Special Forms of Partial Atrioventricular Septal Defect

Malaligned Atrial Septum or Double-Outlet Right Atrium

Deviation of the atrial septum to the left of the AV junction has been reported rarely (27,28). When this occurs, both the right and left AV valves are visualized from the RA, which is connected to both ventricles through a large primum ASD. If deviation of the atrial septum to the left is extreme, the pulmonary veins may be isolated and obstructed, simulating cor triatriatum. Although the term "double-outlet" RA has been applied to this lesion (29), it is truly a form of AVSD.

Common Atrium

Common atrium is characterized by near absence of the atrial septum. In the presence of two ventricles, it always is associated with an AVSD (30). Cases of common atrium typically are syndromic. The most common syndromes are asplenia, polysplenia, and Ellis-van Creveld (9–11). The pathologic spectrum of this lesion ranges from patients with coexistent primum and secundum ASDs to others who lack the entire septum except for a small muscular cord. Patients with syndromes and common atrium frequently have concomitant complex congenital heart disease. In these cases, transposition of the great arteries, double-outlet RV, univentricular AV connection, and anomalous pulmonary venous connections often are encountered. Patients with common atrium frequently have anomalies of cardiac and abdominal situs as well as asplenia.

Clinical Manifestations. Most patients with common atrium present in infancy with symptoms of excess pulmonary blood flow, fatigue, tachypnea, and failure to thrive. However, if increased pulmonary vascular resistance develops, the left-to-right shunt decreases and somatic growth improves. In general, these patients are symptomatic earlier in life than patients with only a primum ASD. The radiographic and electrocardiographic characteristics of patients with common atrium are indistinguishable from those with other forms of AVSD.

Echocardiography. The subcostal four-chamber imaging plane is most suitable for accurate diagnosis. A muscle bundle or band coursing through the atrium should not be misinterpreted as an atrial septum.

Cardiac Catheterization and Angiography. The hemodynamic diagnosis of common atrium depends on the demonstration of complete mixing of systemic and pulmonary venous blood. The oxygen saturations of pulmonary and systemic arterial blood are nearly identical. Pulmonary blood flow exceeds systemic flow, except in patients with severe pulmonary vascular obstructive disease. Right ventricular pressure is increased more often than in secundum ASD or partial AVSD. If definitive repair is delayed, significant pulmonary vascular obstructive disease may develop at an earlier age than in patients with isolated secundum ASD or partial AVSD.

Treatment. Prior to surgical repair, medical therapy usually is instituted when signs and symptoms of excess pulmonary blood flow and failure to thrive are present. Digoxin and diuretic therapy are traditional forms of therapy. Common atrium requires surgical repair, which should be performed early in life because patients usually have symptoms and there is a risk for early development of pulmonary vascular obstructive disease.

COMPLETE ATRIOVENTRICULAR SEPTAL DEFECT

Pathology

The complete form of AVSD is characterized by a large septal defect with interatrial and interventricular components and a common AV valve that spans the entire septal defect (30) (Fig. 29.14). The septal defect extends to the level of the membranous ventricular septum, which is usually deficient or absent.

The common AV valve has five leaflets. The posterior bridging leaflet drapes over the inlet ventricular septum and conceptually represents fusion of the septal tricuspid leaflet and the inferior half of the anterior mitral leaflet. Two lateral leaflets correspond to the posterior tricuspid and posterior mitral leaflets in a normal heart. The right-sided anterior leaflet, in essence, represents the normal anterior tricuspid leaflet, and the so-called anterior bridging leaflet corresponds to the superior half of the anterior mitral leaflet. The extent to which the anterior bridging leaflet actually straddles into the RV varies considerably and has formed the basis for a classification system of complete AVSD into types A, B, and C (see below). The common AV valve may be divided into distinct right and left orifices by a tongue of tissue that connects the two bridging leaflets, representing the rare intermediate form of complete AVSD.

Beneath the five commissures are five papillary muscles. The two left-sided papillary muscles are oriented closer together than in a normal heart, such that the lateral leaflet is smaller than a normal posterior mitral leaflet. In addition, the two papillary muscles often are rotated counterclockwise, such that the posterior muscle is farther from the septum than normal and the anterior muscle is closer to the septum. This papillary muscle arrangement, in conjunction with prominence of an anterolateral muscle bundle, may contribute to progressive LVOT obstruction. Moreover, the leaflets are prone to develop progressive regurgitation and, with time, they become thickened and exhibit hemodynamic and structural changes similar to that associated with mitral valve prolapse (31).

The potential for interventricular shunting exists along the septal surface between the two bridging leaflets and at the interchordal spaces beneath the leaflets. The posterior bridging leaflet characteristically overhangs the ventricular septum and has extensive septal chordal attachments. Occasionally, chordal fusion obliterates the interchordal spaces beneath this leaflet. The anatomic relationship between the anterior bridging leaflet and the ventricular septum is variable and forms the basis for a classification described by Rastelli et al. (32) (Fig. 29.15).

Rastelli Classification for Complete Atrioventricular Septal Defect

Giancarlo Rastelli died in 1970 at 36 years of age (33). During his abbreviated life and brilliant but short career, he made many landmark contributions to the field of congenital heart disease. In the 1960s, he devoted much of his time to obtaining a better understanding of the morphology of the common AV valve in patients with AVSD. The classification scheme that now bears his name was based on the morphology of the anterior bridging leaflet. The improved understanding of the AV valve diversity aided surgeons and improved operative mortality for these patients. Prior to 1964, hospital mortality for patients with AVSD was 60%. Rastelli et al. (34) from the Mayo Clinic published their work in 1968 and operative mortality between 1964 and 1967 decreased to 20%. The classification scheme that Rastelli described is listed below and summarized in Table 29.2.

In type A (most common), the anterior bridging leaflet inserts entirely along the anterosuperior rim of the ventricular

septum. It forms a true commissure with the right-sided anterior leaflet. Beneath this commissure is either a distinct medial papillary muscle or, more commonly, multiple direct chordal insertions along the septum. Interventricular communication beneath the anterior bridging leaflet may be minimal or absent in some cases owing to extensive interchordal fusion.

In type B (least common), the anterior bridging leaflet is larger and the right-sided anterior leaflet is smaller than in type A. As a result, the bridging leaflet straddles the septum and is associated with papillary muscle attachment along the septal or moderator band in the RV. Because chordal anchors are not present between the anterior bridging leaflet and the underlying ventricular septum, free interventricular communication exists.

In type C, the anterior bridging leaflet is larger than in type B, and its medial papillary muscle attachments fuse to the right-sided anterior papillary muscle. As a result, this leaflet is generally very small. Because the anterior bridging leaflet is not attached to the ventricular septum, free interventricular communication is possible, and the leaflet has been described as “free floating.”

The subtype of complete AVSD has some bearing on the likelihood of associated lesions. Type A usually is an isolated defect and is frequent in patients with Down syndrome. In contrast, type C is encountered with other complex anomalies, such as tetralogy of Fallot, double-outlet RV, complete transposition of the great arteries, and heterotaxy syndromes (35,36). Coronary artery anomalies, when they occur, tend to be associated with coexistent conotruncal malformations rather than the AVSD. The combination of type C complete AVSD with tetralogy of Fallot is observed in patients with Down syndrome, whereas double-outlet RV is a feature of patients with asplenia.

Clinical Manifestations

Tachypnea and failure to thrive invariably occur early in infancy as a result of excessive pulmonary blood flow. Virtually all patients with complete AVSD have symptoms by 1 year of age. If these symptoms do not develop early on, the clinician should suspect premature development of pulmonary vascular obstructive disease. AV valve regurgitation compounds these problems. After surgical repair, left AV valve regurgitation is the most common reason for reoperation. A recent study demonstrated that 22% of patients who had undergone repair of complete AVSD had more than moderate left AV valve regurgitation at 6 month follow-up (2). Although single-center reports have identified preoperative AV valve regurgitation as an important risk factor for reoperation (37), it failed to predict greater than moderate postoperative AV regurgitation in the PHN study (2). Greater than moderate AV valve regurgitation within 1 month of surgery was a strong predictor of persistent AV regurgitation at 6 month follow-up. Regression of postoperative left AV valve regurgitation was not demonstrated in that study (2) in contrast to anecdotes that this occurs.

If severe pulmonary vascular obstructive disease is absent, there may be no systemic arterial oxygen desaturation. The physical examination demonstrates a hyperactive precordium and an accentuated first sound, and the second sound may move with respiration but it is quite variable. Because of elevated pulmonary artery pressures, the pulmonary closure sound is accentuated. A loud S1-coincident holosystolic murmur can be heard along the lower left sternal border and at the cardiac apex if left AV valve regurgitation is present. A separate crescendo-decrescendo systolic ejection murmur is heard over the upper left sternal border as a result of increased pulmonary blood flow. A middiastolic murmur can be heard along the lower left sternal border and frequently at the apex

Figure 29.14. Complete AVSD. **A:** Right anterior oblique view with right atrial and right ventricular free walls removed, demonstrating a large septal defect. **B:** Left posterior oblique view (same specimens as in **A**) with left atrial and left ventricular free walls removed, showing the same septal defect. **C:** Short-axis view, illustrating a type A common AV valve with five leaflets. **D:** Four-chamber view, showing secondary right ventricular hypertrophy and right atrial dilation. **E:** Short-axis view of a biventricular specimen removed during cardiac transplantation, showing an unbalanced form of AVSD with dilation of a common inlet RV, leftward septal bowing, and a hypoplastic LV. **F:** Four-chamber view of a complete AVSD associated with right atrial isomerism, mirror-image ventricles (L-loop ventricular inversion), and asplenia. Ao, aorta; CS, coronary sinus; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Figure 29.15. Anatomic and echocardiographic features of complete AVSD based on the Rastelli Classification. A: Type A complete AVSD. The defect is characterized by insertion of the anterior bridging leaflet to the crest of the ventricular septum (VS). B: Type B complete AVSD. The defect is characterized by dominant insertion of the anterior leaflets into papillary muscles in the RV. In this example, the anterior bridging leaflet inserts onto the crest of the ventricular septum, as well as onto a large ventricular papillary muscle (P) (arrow in echocardiogram). C: Type C AVSD. The anterior leaflet is unattached (arrow) and overrides the crest of the ventricular septum. The free anterior leaflet does not insert onto the crest of the ventricular septum. A, anterior; P, posterior; L, left; LA, left atrium; LV, left ventricle; R, right; RA, right atrium; S, superior. (Modified from Seward JB, Tajik AJ, Edwards WD, et al. *Two-Dimensional Echocardiographic Atlas. Vol. 1. Congenital Heart Disease.* New York, NY: Springer-Verlag, 1987:270–292, with permission.)

as a result of increased blood flow across the common AV valve. However, the physical examination findings of complete AVSD may be indistinguishable from those of an uncomplicated large VSD or partial AVSD.

Echocardiography

Two-dimensional echocardiography is the primary diagnostic tool for evaluation of complete AVSD (19,20,38). As described earlier, assessment of the internal cardiac crux from the apical and subcostal four-chamber projections provides excellent detail of the size and locations of defects in both the atrial and ventricular septa (Fig. 29.16). Additional secundum ASD, a fairly common associated finding, can be detected from the subcostal four-chamber coronal view and with clockwise rota-

tion of the transducer from the subcostal sagittal imaging plane (21). The VSD is located posteriorly in the inlet septum. Both right- and left-sided components of the common AV valve are displaced toward the ventricles and are associated with variable deficiency of the inflow ventricular septum. A PDA is a common associated finding. In the PHN report, 44% of patients had PDA ligation at the time of AVSD repair. Suprasternal notch and high left parasternal imaging should be performed to evaluate the PDA. However, in the setting of massive pulmonary blood flow from a complete AVSD, aliased color Doppler signals in the branch pulmonary arteries may make small PDAs difficult to appreciate. Fortunately, surgeons routinely check for ductal patency at the time of AVSD repair. Spectral and color Doppler serve as adjuncts to assess the sites of shunting, severity of AV valve regurgitation, and connections of the pulmonary veins. Fetal echocardiography readily detects complete AVSD in standard four-chamber views (Fig. 29.17).

When communicating with a surgeon, the echocardiographer must describe the morphology of the AV valve in precise detail. The surgeon needs to know the competence and ventricular commitment of the AV valve orifices and whether a tongue of tissue connects the superior and inferior bridging leaflets to form two distinct orifices. The subcostal *en face* view is essential for this determination. This view is obtained with counterclockwise rotation from the four-chamber coronal view until the AV valve leaflets appear *en face* (Fig. 29.18). Deliberate superior and inferior angulation of the probe will permit inspection of the cross section of all five valve leaflets. The valve is inspected from the inferior margin of the atrial septum to the superior margin of the ventricular septum (38). In the operating room, the TEE transgastric short-axis view will aid in this assessment.

A single left ventricular papillary muscle may occur in complete AVSD. Similar to the double-orifice valve, a single papillary muscle will reduce the effective valve area and complicate the surgical repair. Left AV valve repair may be

TABLE 29.2 Rastelli Classification for Complete AVSD	
Rastelli Type	Anterior Bridging Leaflet and Chordae
A	Divided and attached to crest of ventricular septum. Multiple chordae.
B	Partly divided, not attached to crest of the septum. Chordae attach to papillary muscle in RV usually on septal surface
C	Not divided and not attached to the crest of the septum (“free floating”). Chordae attach to papillary muscle on RV free wall

Figure 29.16. Complete AVSD: Apical four-chamber images in systole (left) and diastole (right) demonstrating a complete AVSD with large primum ASD (*asterisk*), large inlet VSD (*arrow*), and common single-orifice AV valve. The **right panel** demonstrates the valve opening as a single unit with only lateral “hinge points” visible in this image. Biventricular volume overload and a small secundum ASD are present in this patient.

compromised further by relative leaflet hypoplasia. Echocardiographic imaging techniques for this abnormality are similar to those for double-orifice left AV valve.

The Concept of “Balance”

Two-dimensional echocardiography is essential for determining the relative sizes of the ventricles. In AVSD, the AV valves (regardless of number of orifices) may be more committed to one ventricle at the expense of flow into the other. This will lead to relative hypoplasia of the underperfused ventricle. Both partial and complete AVSDs can be “balanced” or “unbalanced” based on how the AV junction is shared by the ventricles. If the AV inlet is equally shared by both ventricles, then this is consistent with a “balanced” AVSD.

In *unbalanced* AVSD, one ventricle is typically hypoplastic, although the common AV valve is its usual size (Fig. 29.19). The larger ventricle is termed the “dominant” ventricle. Unbalanced AVSD occurs in approximately 10% of all AVSDs. Two-thirds of unbalanced AVSDs are right ventricular dominant. When the RV is dominant, the LV is hypoplastic, and more than half of the AV junction is committed to the RV. These patients frequently have severe coarctation of the aorta and aortic arch anomalies. Conversely, unbalanced AVSD with a dominant LV has a hypoplastic RV and is associated with

pulmonary valve stenosis or atresia. Interestingly, in children with Down syndrome and unbalanced AVSD, left ventricular dominance is common.

With standard 2-D echocardiographic imaging, both ventricles are appreciated from the apical four-chamber view. This imaging plane allows visualization of malalignment between the atrial and ventricular septa. This can be a clue to an unbalanced AVSD. The subcostal sagittal view gives an estimate of the proportion of the AV valve committed to each ventricle. Determining “balance” with echocardiographic imaging is important as it forms the basis for deciding single-ventricle versus biventricular surgical repair. Modest degrees of right ventricular hypoplasia also may be addressed with a “1.5-ventricle repair.” In this situation, intracardiac shunts are repaired and the RV is unloaded by performing a bidirectional cavopulmonary connection.

Cohen et al. (39) (Fig. 29.20) proposed a quantitative approach using the subcostal sagittal view to delineate cases with significant left ventricular hypoplasia that may be better treated with a single-ventricle approach. They measured the area of the AV valve apportioned over each ventricle and calculated an AV valve index (AVVI). This serves as an LV/RV area ratio. The AVVI may be used as the basis for an algorithm to stratify patients into a single-ventricle versus a two-ventricle surgical pathway. Those with an AVVI <0.67 who have a large VSD would be considered for the single-ventricle pathway.

Figure 29.17. A 31-week gestation fetal echocardiogram with severe common AV valve regurgitation: four-chamber images in diastole (left), systole (center), and systole with color Doppler (right) demonstrating a common atrium, common AV valve, and common ventricle. After delivery, this child was found to also have asplenia.

Figure 29.18. Subcostal sagittal imaging of common AV valve: Subcostal sagittal images in systole (left) and diastole (right) in a patient with complete AVSD. The right panel demonstrates the anterior bridging leaflet (arrow) of the common AV valve. This leaflet crosses (bridges) the VSD anteriorly and is shared by both ventricles. It is not divided into right and left components and has no attachments to the ventricular septum. This morphology is also called free floating or Rastelli type C. During repair, unlike the naturally divided anterior bridging leaflet (type A), this leaflet must be incised into right and left components before attachment to the VSD patch.

The clinician must be aware of several caveats that may make interpretation of “ventricular balance” less straightforward. For example, the severity of valve malalignment may not necessarily correlate with the degree of ventricular hypoplasia. Moreover, pulmonary venous blood preferentially crosses the ASD causing underfilling of the LV. Finally,

the presence of a large left-to-right shunt may cause severe right ventricular enlargement with bowing of the septum to the left. This will lend an appearance of “hypoplasia” to the LV. van Son et al. (40) attempted to estimate the “potential volume” of the LV preoperatively by using a theoretical model that calculates the relative areas of the LV and

Figure 29.19. Right versus left ventricular dominance, based on a classification scheme from Bharati and Lev: Left ventricular dominance (left panels) and right ventricular dominance (right panels) are demonstrated. In the LV-dominant case, the common AV valve opens predominantly into the LV. Conversely, in the RV-dominant case, the common AV valve opens predominantly into the RV. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

LV Dominant

RV Dominant

Figure 29.20. Echocardiographic assessment of ventricular dominance: Assessing unbalanced AVSDs using AV valve area measurements. **Left panel:** Diastolic frame from the subcostal sagittal plane demonstrating an en face view of the common AV valve. The planimetry demonstrates relative balance between the right and left portions of the common valve. **Center panel:** Diastolic frame demonstrating an RV-dominant unbalanced AVSD with relative dominance of the right portion of the common AV valve. **Right panel:** Companion systolic frame of an RV-dominant AVSD. (From Cohen M, Jacobs ML, Weinberg PM, et al. Morphometric analysis of unbalanced common atrioventricular canal using two-dimensional echocardiography. *J Am Coll Cardiol* 1996;28:1017, with permission.)

RV in short axis after assuming normal septal configuration (Fig. 29.21).

All of these methods should be employed when assessing a patient with an unbalanced AVSD. One must realize that none of these methods factor in patient/cardiac growth. It also is important to know if the LV is apex forming. Generally patients with

unbalanced AVSD may present many challenges both from the echocardiographic imaging and clinical management perspectives.

Radiography

The heart usually is enlarged in patients with complete AVSD. Enlargement of the RA is suggested by increased convexity of the right heart border, and left atrial enlargement may produce a characteristic flattening of the left heart border. The pulmonary artery is prominent, and the pulmonary vascular markings are increased.

Electrocardiography

Prolongation of the P-R interval is observed in approximately 25% of patients with AVSD (25). Intracardiac studies have revealed increased intra-atrial or AV node conduction times as the cause of P-R prolongation. More than 50% of patients meet voltage criteria for atrial enlargement. A superior or northwest QRS axis is common (Fig. 29.22). The QRS axis in the frontal plane lies between -60 degrees and -135 degrees, with most patients having an axis between -90 degrees and -120 degrees. Most patients have an rsR, RSR', or Rr' in lead V1, and others have a qR or R pattern in the same chest lead, all indicating right ventricular hypertrophy. Left ventricular hypertrophy may also be present.

Figure 29.21. Short-axis assessment of septal flattening in unbalanced AVSD. Due to right ventricular volume overload, the septum bows toward the LV. This may provide the misperception that the LV is hypoplastic. However, if one assumes normalization of septal position, the potential volume of the LV after repair may be predicted. (From van Son JAM, Phoon CK, Silverman NH, et al. Predicting feasibility of biventricular repair of right-dominant unbalanced atrioventricular canal. *Ann Thorac Surg* 1997;63:1657, with permission.)

Cardiac Catheterization and Angiography

Cardiac catheterization and angiography rarely are needed for management of infants with complete AVSD. In an older child, when pulmonary vascular obstructive disease is suspected, there is a role for determining pulmonary vascular resistance. Severe pulmonary vascular obstructive disease (pulmonary vascular resistance of >10 U·m²) is rare but has been reported in infants <1 year of age.

Figure 29.22. A 12-lead ECG from a 3-month-old with complete AVSD. Left axis deviation and right ventricular hypertrophy are present.

Cardiac catheterization demonstrates increased oxygen saturation at both the right atrial and the right ventricular levels. In complete AVSD, pulmonary artery systolic pressure invariably is at or near systemic level. However, in partial AVSD, pulmonary artery systolic pressure usually is <60% of systemic pressure. Pulmonary blood flow is increased as a result of left-to-right shunting at both atrial and ventricular sites, and the degree of shunting depends upon the relationship of pulmonary to systemic vascular resistance. The hemodynamic abnormality in complete AVSD may be complicated by severe common AV valve regurgitation, allowing blood to shunt freely among all cardiac chambers. Left ventricular angiography rarely is required but reveals the typical LVOT gooseneck deformity and varying severity of left AV valve regurgitation.

Clinical Course

Infants with complete AVSD typically will require medical therapy with diuretics, sometimes augmented with digoxin or angiotensin-converting-enzyme inhibitors depending on the specific clinical situation. The timing of surgical intervention must take into account the propensity of pulmonary vascular disease to develop in these patients at an early age. The decision for operation is usually made in the first 6 months of life. Children with complete AVSD frequently have surgical repair between 3 and 6 months of age. But, children with Down syndrome may require surgical intervention at an earlier age due to their propensity to develop pulmonary vascular obstructive changes.

Special Forms of Complete Atrioventricular Septal Defect

Intermediate Defect

A rare subtype of complete AVSD occurs when the anterior and posterior bridging leaflets are fused atop the ventricular septum and the common AV valve is divided into distinct right and left orifices. This defect usually has a large primum ASD and a large inlet VSD. Patients present in the same manner as with other forms of complete AVSD. Surgical repair does not have to include division of separate right

and left AV valve components (this has occurred naturally). The cleft in the left AV valve is closed, but the bridging leaflets often have insufficient tissue to reconstruct a competent anterior leaflet.

Down Syndrome and Atrioventricular Septal Defect

Down syndrome occurs in more than half of patients with complete AVSD. Children with Down syndrome and complete AVSD also are more likely to have associated tetralogy of Fallot (41,42). In contrast, sidedness (situs) and splenic anomalies are rare in patients with Down syndrome. Patients with Down syndrome usually do not have associated LVOT obstruction, left ventricular hypoplasia, coarctation of the aorta, or additional muscular VSDs (43,44). In cases with unbalanced AVSD, patients with Down syndrome have LV dominant morphology more frequently than RV dominance.

The extent and progression of pulmonary vascular changes in children with Down syndrome and complete AVSD remain controversial. Histologic studies (45) have failed to show any differences in the extent of pulmonary vascular changes when patients with Down syndrome were compared with normal children who also had AVSD. Other studies (46,47) have suggested that children with Down syndrome have relative pulmonary parenchyma hypoplasia and develop pulmonary vascular obstructive disease appreciably earlier than patients with normal chromosomes and complete AVSD.

The hemodynamic assessment of children with Down syndrome must take into account that these patients may have chronic nasopharyngeal obstruction, relative hypoventilation, and sleep apnea. These factors contribute to carbon dioxide retention, relative hypoxia, and elevated pulmonary vascular resistance.

Patients with Down syndrome have a higher ratio of pulmonary to systemic resistance than patients without Down syndrome (48). This difference resolves with administration of 100% oxygen, suggesting that apparent hypoxia and hypoventilation are factors that can be corrected during hemodynamic study. Fixed and elevated pulmonary vascular resistance has been demonstrated in 11% of Down syndrome patients <1 year of age (48). In the current era, timing of repair and surgical outcome for patients with Down syndrome are similar to those of the general population (2,49).

INITIAL SURGICAL TREATMENT OF AVSD

Partial Atrioventricular Septal Defect

The objectives of surgical repair include closure of the interatrial communication and restoration and preservation of left AV valve competence. These objectives can be accomplished by careful approximation of the edges of the valve cleft with interrupted nonabsorbable sutures. On occasion, it is necessary to add eccentric annuloplasty sutures, typically in the area of the commissures to correct persistent central leaks. The repair is completed by closure of the interatrial communication (usually with an autologous or bovine pericardial patch), avoiding injury to the conduction tissue (50). This repair results in a two-leaflet valve. Rarely, if the left AV valve is considered a trileaflet valve, with the cleft viewed as a commissure, the commissure may be left unsutured and annuloplasty sutures can be placed to promote coaptation of the three leaflets. In the recent PHN study, the cleft was closed in 98% of cases (1).

However, the morphologic concepts and surgical methods favored by Carpentier (51) and Piccoli et al. (52) continue to be debated. The PHN investigators could not demonstrate that annuloplasty decreased the prevalence of left AV valve regurgitation 6 months after surgery. In that study, 18 of 59 patients (31%) who had 6 month postoperative echocardiography data available demonstrated moderate or greater left AV valve regurgitation (1). Because the details of annuloplasty were not available in all operative reports, the PHN study loosely defined “annuloplasty” as any additional intervention on the left AV valve beyond cleft closure. This limits the ability to assess specific surgical techniques. At Mayo Clinic, the left AV valve cleft is usually closed and, if needed, limited annuloplasty sutures are placed near the commissures to improve valve competence.

The risk of hospital death after surgical repair of partial AVSD is approximately 1% (1). The timing of repair for partial AVSD trended to an earlier age in the PHN study. The median age of repair for patients with partial AVSD was 1.8 years. Long-term survival after repair of partial AVSD is good. In a series of 334 patients from Mayo Clinic, 20- and 40-year survivals after repair of partial AVSD were 87% and 76%, respectively (53). Closure of the left AV valve cleft and age <20 years at time of operation were associated with improved survival. Reoperation was performed for 11% of these patients. Repair of residual/recurrent left AV valve regurgitation or stenosis was the most common reason for reoperation (53). In the PHN study, residual ASD shunts (<1%) and left AV valve stenosis (1%) were rare (1). Residual left AV regurgitation remains the major reason for reoperation. In that study, 31% of patients had at least moderate regurgitation 6 months after surgery for partial AVSD repair. Repair after age 4 years was a risk factor for residual moderate-severe left AV valve regurgitation (1).

A low frequency of postoperative arrhythmias has been noted. The finding of surgical complete heart block has been uncommon and would require permanent pacemaker implantation. Late onset of atrial flutter has been rarely encountered.

Complete Atrioventricular Septal Defect

Surgical repair of complete forms of AVSD is indicated early in life. The median age at time of repair in the recent multicenter report was 3.6 months (2). Repair of complete AVSD must be performed prior to the development of irreversible pulmonary vascular obstructive disease. Repair typically is performed between 3 and 6 months of age. Earlier repair should be considered for infants with failure to thrive.

For the symptomatic infant, surgical options include palliative pulmonary artery banding or complete repair of the anomaly. Silverman et al. (54) reported excellent results of pulmonary artery banding in 21 infants with complete AVSD who were <1 year of age. In that series, there was one surgical death (5%), and the remaining patients had excellent palliation. Williams et al. (55) recommended pulmonary artery banding for infants weighing <5 kg who were unresponsive to medical treatment or had significant associated anomalies. In the modern era, most centers perform complete repair in small infants who fail to thrive. This approach has largely obviated the need for pulmonary artery band placement. Investigators in the PHN study found that age at repair <2.5 months frequently was associated with concurrent procedures that likely drove the early timing of surgery. In that study, infants who required early repair had similar outcomes in respect to residual shunts and severity of left AV valve regurgitation, but they were more likely to require circulatory arrest, prolonged intensive care unit stays, and increased duration of hospitalization due to their comorbidities (2).

The objectives of surgical repair include closure of interatrial and interventricular communications, construction of two separate and competent AV valves from available leaflet tissue, and repair of associated defects. Techniques for the surgical repair of complete AVSD have been standardized and are based on the use of a single patch or double patch (separate atrial and ventricular patches) to close the ASD and VSD and then reconstruction of the left AV valve as a bileaflet valve. (Figs. 29.23, 29.24) Puga and McGoon (56) have described these techniques in detail. Piccoli et al. (52) and Studer et al. (57) consider the cleft of the left AV valve to be a true commissure and envisioned this valve as a trileaflet valve. On the basis of these concepts, Carpentier (51) preferred the two-patch technique and the left AV valve remained a trileaflet structure (Fig. 29.25). More recently, the “Australian” single-patch technique with primary suture closure of the VSD and pericardial patch closure of the ASD has been described (58,59).

Investigators in the PHN study evaluated the various surgical techniques utilized to repair complete AVSD (2). In that study, the cleft was closed in 93% of cases. The two-patch technique was used in 72% of cases, the single-patch technique in 18%, and the Australian repair in 10%. Choice of repair depended on surgeon/center preference. The Australian technique was used in younger patients and required return to cardiopulmonary bypass (CPB) more frequently than the single- or two-patch techniques. The single-patch technique had longer CPB and aortic cross-clamp times but no patients repaired with this technique needed to return to CPB. Operative mortality, hospital stay, residual shunt, and significant left AV valve regurgitation were similar with all techniques (2).

In the modern era, hospital mortality was 2.5% (2). Left AV valve regurgitation was the most common reason for reoperation and occurred in 4% of cases within 6 months of initial repair. Similar to previous reports, approximately 25% of patients had at least moderate residual left AV valve regurgitation. Residual shunts were rare and usually closed spontaneously within 6 months.

At most centers, the current approach is to offer repair for complete AVSD at age 3 to 6 months. If a child is failing to thrive or has excessive pulmonary blood flow or heart failure, repair is offered at an earlier age. Surgeons at many North American centers prefer to utilize a two-patch technique thereby avoiding division of the bridging leaflets (60) (Figs. 29.23 and 29.24). If the VSD is shallow, a single-patch technique is considered with primary VSD closure (Australian technique) (Fig. 29.25). The left AV valve cleft typically is closed and eccentric annuloplasty sutures are utilized to gain valve competence. Intraoperative TEE is utilized in all AVSD cases. If TEE demonstrates more than mild left AV valve regurgitation, then CPB is resumed and aggressive attempts are made to improve valve competency (61).

Figure 29.23. The traditional *single-patch* repair of complete AVSD (surgical view from the RA). Note that one patch is utilized to close both the VSD and ASD. The ventricular component of the single patch is seen deep to the AV valves. This patch is positioned by dividing the bridging leaflets. Once the patch is sutured into place, the bridging leaflets are resuspended to the patch. The cleft in the left AV valve has been closed.

Figure 29.24. The *two-patch* technique for complete AVSD (surgical view from the RA). The first patch is utilized to close the VSD and is demonstrated deep to the AV valves. The bridging leaflets are *not* divided. Once the VSD patch is placed and the cleft is repaired, a second patch is utilized for ASD repair.

Figure 29.25. The modified single-patch or *Australian technique* (surgical view from the RA). The bridging leaflets are sutured down directly to the VSD crest. Note that the AV valve leaflets appeared "tucked" to the crest of the septum. Once this is performed, a single patch is utilized to repair the remaining ASD.

Special Problems in Complete AVSD Surgery

Parachute Deformity of the Left AV Valve. This problem has been addressed by David et al. (62). With such a deformity, closure of the cleft at the time of repair may result in an obstructed orifice. If the patient has significant left AV valve regurgitation with a parachute deformity, then valve replacement may be the only suitable option.

Double-Orifice Left AV Valve. The surgeon must resist the temptation to join the two orifices by incising the intervening leaflet tissue. The combined opening of both orifices is satisfactory for adequate left AV valve function (63).

Right or Left Ventricular Hypoplasia. These anomalies may be severe enough to preclude septation. The only option for definitive surgical treatment is the modified Fontan procedure preceded by adequate pulmonary artery banding in infancy (64).

Tetralogy of Fallot. In patients with this anomaly, all of whom have complete AVSD, the infundibular septum is displaced anteriorly, so that the inlet VSD extends anteriorly and superiorly toward the perimembranous area. In tetralogy of Fallot, there is obstruction of the right ventricular outflow tract. These cyanotic infants often initially are treated with a systemic-to-pulmonary artery shunt and then with "complete repair" at 2 to 4 years of age. The intracardiac repair of these hearts is best accomplished through a combined right atrial and right ventricular approach (42).

Subaortic Stenosis. If discovered at the time of initial preoperative evaluation, subaortic stenosis tends to be of the fibromuscular membrane type and should be treated by appropriate resection during surgical repair. However, subaortic stenosis may appear late after surgical repair of AVSD. The

stenosis may be related to the uncorrected deficiency in the inlet septum. The obstruction usually is due to the formation of endocardial fibrous tags and fibromuscular ridges. Usually it can be treated by local resection, although in some patients, a modified Konno procedure may be necessary (65–68).

REOPERATION AFTER REPAIR OF ATRIOVENTRICULAR SEPTAL DEFECT

Partial Atrioventricular Septal Defect

Late reoperation following repair of partial AVSD may be required for regurgitation or stenosis of the left AV valve, subaortic stenosis, regurgitation of the right AV valve, or residual ASD. Reoperation for left AV valve regurgitation occurs in 10% to 15% of survivors of primary repair of partial AVSD. Risk factors for reoperation include significant residual left AV valve regurgitation as assessed intraoperatively at the time of initial repair, the presence of a severely dysplastic valve, and failure to close the cleft in the anterior (septal) leaflet. Repeat valve repair is possible if the dysplasia is not severe or when the mechanism of regurgitation is through a residual cleft. Eccentric commissural annuloplastic sutures often are needed to correct central regurgitation. Replacement of the valve may be required in the presence of a severe dysplasia.

Reoperation for left AV valve stenosis may be necessary if the valve orifice is hypoplastic, or if the orifice is restricted owing to a parachute deformity of the subvalvular apparatus. Patient–prosthetic mismatch in patients who required valve replacement during infancy or early childhood will merit valve re-replacement. Relief of prosthetic left AV valve stenosis resulting from a small annulus is technically challenging. The small valve requires replacement with a larger prosthesis, and there are no reliable techniques for annular enlargement. Thorough debridement and excision of fibrous scar and old prosthetic material is necessary. In rare circumstances, the new larger prosthesis is sewn into the LA in a supra-annular position.

Late LVOT obstruction owing to subaortic stenosis occurs more frequently after correction of partial AVSD than with complete AVSD. This is likely due to the fact that during the conventional repair, the deficient portion of the inlet ventricular septum is not reconstructed so that the anterior (septal) leaflet of the left AV valve hinges on the line of fibrous fusion to the crest of the ventricular septum. Thus, the standard surgical repair does not modify the elongated and potentially narrowed LVOT. This is in contrast to complete AVSD in which the deficient inlet septum is reconstructed with the subvalvular patch that effectively widens the outflow tract. Relief of LVOT obstruction can be accomplished in several ways, including transaortic resection of the fibrous or fibromuscular membrane

and patch enlargement of the LVOT with a transaortic and right ventricular approach (modified Konno procedure). Others have described alternative approaches, including reconstruction of the deficient inlet septum, septal myectomy, and apicoaortic conduits (65–68). Reoperation for an isolated residual or recurrent ASD is rare after repair of partial AVSD.

Stulak et al. (69) recently reported the Mayo Clinic experience with 93 patients who had reoperation after initial repair of partial AVSD. Average time to reoperation was 10 years. The most common indications for reoperation were left AV valve regurgitation (67%), subaortic stenosis (25%), right AV valve regurgitation (22%), and residual ASD (11%). Reoperations included left AV valve repair or replacement, subaortic resection, and right AV valve repair. There was no difference in survival when comparing left AV valve repair (38 patients) with replacement (35 patients).

Complete Atrioventricular Septal Defect

Late reoperation following repair of complete AVSD occurs in approximately 20% of patients during the first 20 years after surgical repair. Lesions requiring reoperation include left and right AV valve regurgitation, left AV valve stenosis (native and prosthetic), and residual ASDs or VSDs.

Residual left AV valve regurgitation may result from inadequate surgical reconstruction. Intraoperative TEE helps guide the surgical repair thereby preventing patients from leaving the operating room with significant residual left AV valve regurgitation. Right AV valve regurgitation requiring reoperation is rare after repair of complete AVSD. It occurs in the presence of pulmonary hypertension or in association with tetralogy of Fallot with right ventricular dysfunction and pulmonary valve regurgitation or stenosis. Residual shunts are rare causes for late reoperation after initial repair of complete AVSD.

Investigators at the Mayo Clinic recently assessed reoperation in 50 patients after repair of complete AVSD (70). The most common indication for reoperation was left AV valve regurgitation (41 patients). Similar to the PHN data, left AV valve stenosis was rare (1 patient). Half of this cohort underwent left AV valve re-repair and the other half had valve replacement. Long-term survival was 86% at 15 years after the reoperation.

POSTOPERATIVE ECHOCARDIOGRAPHIC ASSESSMENT

Echocardiographic assessment of the patient after repair of an AVSD includes evaluation of the morphology of the AV valves (Fig. 29.26) and determination of right and left AV valve stenosis or regurgitation (71). A search for residual shunts should be performed. Doppler evaluation of the velocity profiles across a ventricular level shunt and right AV valve regurgitation can

Figure 29.26. Left: Four-chamber anatomic specimen of a patient with partial AVSD after patch closure of a primum ASD and repair of a cleft mitral valve. The patch (arrow) is attached to the right side of the atrial septum and the right AV valve to avoid damage to the conduction tissue and left AV valve. Right: corresponding apical four-chamber echocardiograph. L, left; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; S, superior.

provide accurate determination of right ventricular systolic pressure. However, in the setting of a residual VSD, the VSD jet may contaminate the right AV valve regurgitation signal and preclude accurate quantification of right ventricular systolic pressure. In that setting, the echocardiographer should use indirect techniques such as assessment of ventricular septal flattening or bowing, right ventricular size and function, and Doppler interrogation of the pulmonary regurgitation velocity waveforms to assess pulmonary artery diastolic pressure. Meticulous assessment of progressive left AV valve regurgitation and progression of LVOT obstruction must be performed during serial postoperative evaluations.

THE ADULT WITH ATRIOVENTRICULAR SEPTAL DEFECT

Previously Undiagnosed Adults with Atrioventricular Septal Defect

When discovered in adulthood, patients with partial AVSD will present with symptoms of exercise intolerance, dyspnea on exertion, or palpitations from a new atrial arrhythmia. These patients may exhibit the typical physical exam findings of an ASD (systolic ejection murmur at the left upper sternal border, widely split and fixed second heart sound, and a diastolic rumble along the left sternal border due to increased flow across the right AV valve). Adults with previously undiagnosed partial AVSD may come to diagnosis when a chest x-ray or electrocardiogram is performed for other reasons. The chest x-ray may demonstrate cardiomegaly, and the electrocardiogram often shows left axis deviation. A regurgitant S1-coincident holosystolic murmur (due to the cleft in the anterior leaflet of the left AV valve) may also prompt echocardiographic evaluation. Left AV valve stenosis is a rare finding in adults with unrepaired partial AVSD. If left AV stenosis is present, these patients usually have a single papillary muscle and morphology of a parachute valve. Surgical repair of partial AVSD is recommended if discovered in adulthood in the absence of significant pulmonary hypertension.

Echocardiography of adults with AVSD should be performed in an imaging laboratory with extensive congenital heart disease experience. The role of cardiac catheterization for some patients is to evaluate coronary artery anatomy or for calculation of pulmonary vascular resistance. One would prefer the pulmonary arteriolar resistance (rPa) to be <7 units- m^2 to safely consider repair of a partial AVSD in adulthood. If the rPa is elevated above this level, then provocative testing in the catheterization laboratory with the use of pulmonary vasoactive agents such as nitric oxide is indicated. That said, patients with rPa as high as 15 units- m^2 have undergone successful surgery for isolated ASD (72). In this select group of patients, one would consider pre- and postoperative treatment with pulmonary vasoactive agents such as bosentan, sildenafil, or Flolan and documentation via hemodynamic catheterization of a substantial improvement in rPa during this therapy. In patients older than age 40 years, regardless of symptoms, noninvasive assessment of coronary artery disease typically is performed prior to surgery. Selective coronary angiography or CT angiography may be indicated if noninvasive coronary assessment is abnormal. Primum ASDs are not amenable to closure with commercially available transcatheter devices. Minimally invasive robotic techniques have been used to repair isolated mitral valve clefts but, thus far, not in the setting of AVSD.

Adults with Previously Repaired Atrioventricular Septal Defect

Surgery for the repair of partial AVSD should be performed by surgeons with training and expertise in congenital heart

disease (73). Surgical reoperation is recommended in adults with previously repaired AVSD for the following reasons:

1. Need for left AV valve repair or replacement due to symptomatic regurgitation or stenosis, arrhythmia, increase in LV dimensions, or LV dysfunction
2. LVOT obstruction with a mean gradient >50 mm Hg or a Doppler-derived maximum instantaneous gradient >70 mm Hg. LVOT obstruction with a mean gradient <50 mm Hg but associated with significant mitral or aortic valve regurgitation
3. Residual or recurrent ASD or VSD with a significant left-to-right shunt

Reoperation on the left AV valve does not necessarily dictate that valve replacement will be needed. In the recent study from the Mayo Clinic, only half of the patients required left AV valve replacement at the time of the second operation (70). Interestingly, left AV valve replacement did not preclude further reoperation in these patients.

Recommendations for Pregnancy

All women with a history of AVSD should be evaluated when first contemplating pregnancy to ensure that there are no significant residual hemodynamic problems that may complicate their management. Pregnancy usually is well tolerated by women who have had successful repair of AVSD. In addition, for women with unrepaired partial AVSD, the left-to-right shunt and the left AV valve regurgitation usually are well tolerated during pregnancy. The data from the CARPREG study (74) and a more recent follow-up to that database (75) demonstrated that women with repaired and unrepaired left-to-right shunt lesions generally tolerated pregnancy well, except for a few cases of arrhythmia.

However, for women with pulmonary vascular obstructive disease and severe pulmonary artery hypertension (pulmonary artery systolic pressure > 60 mm Hg), pregnancy is not advised. Adult patients with unrepaired complete AVSD typically have Eisenmenger physiology. Fortunately with the advances in surgical techniques and improved outcomes over the last four decades, presentation in adulthood with unrepaired AVSD and Eisenmenger physiology is rare.

Patients who had repair of partial or complete AVSD require lifelong cardiology follow-up. Preferably, this should be at centers that specialize in the care of adults with congenital heart disease. At least 15% to 20% of these patients will come to reoperation because of progressive left AV valve regurgitation or LVOT obstruction. LVOT obstruction may occur de novo even if the patient had undergone primary repair of partial AVSD as an adult (24).

Endocarditis prophylaxis is not generally advised based on the 2007 AHA guidelines for uncomplicated vaginal delivery in woman with unrepaired partial AVSD. For women who had repair of AVSD, one would expect to utilize endocarditis prophylaxis only in those who had valve replacement. Fetal echocardiography is recommended at approximately 20 weeks' gestation due to the 3% to 5% recurrence risk of congenital heart disease in offspring when either parent had AVSD.

CONCLUSIONS

The repair of AVSD has been one of the success stories in the field of congenital heart surgery over the last four decades. The pioneering work performed by Giancarlo Rastelli in the 1960s is but one of these accomplishments. In the modern era, adult survival with excellent quality of life is expected for children

born with AVSD. However, 15% to 20% of these patients may face reoperation in their lifetime. All of these patients require lifelong surveillance for development of LVOT obstruction and left AV valve regurgitation.

ACKNOWLEDGMENTS

The authors acknowledge the contributions of the former authors of this chapter (Drs. William Edwards, Francisco Puga, and Robert Feldt). They participated in the landmark research that formed the cornerstone of this chapter during several editions of the textbook. We also appreciate the constructive review of this chapter by Drs. Bryan Cannon and Patrick O'Leary.

Agustin E. Rubio ■ Mark B. Lewin

Except for bicuspid aortic valve, ventricular septal defects (VSDs) are the most common congenital heart lesions in infancy, childhood, and adolescence.

PREVALENCE

Historically, VSDs constituted 20% to 30% of congenital heart defects. They occur in 1.35 to 3.5/1,000 live births (1,2). The incidence of spontaneous closure of isolated VSDs approximated 45% during the first 12 months of life and 22% during childhood. A study of neonates followed for 15 years showed a spontaneous closure rate of 31% uniformly over the first 10 years of follow-up (3). This explains why the diagnosis of VSDs in adulthood is distinctly rare (4).

With the advent of echocardiography, the recognition of VSDs has increased to 5 to 50/1,000 live births (5,6). A recent review of the incidence of congenital heart disease in metropolitan Atlanta between 1998 and 2005 demonstrated a prevalence of muscular VSDs as detected by physical examination and confirmed by echocardiography to be 2.75/1,000 live births for infants (7). VSD is the most common cardiovascular manifestation associated with aneuploidies (trisomy 21, trisomy 18, and trisomy 13). Although there has not been a clear genetic link put forth, it is theorized that multifactorial causality is present (8).

PATHOLOGY

Multiple classification systems have been proposed for the description of VSDs. The classification system described in the subsequent sections utilizes the description of the ventricular anatomy as per Soto et al. and Anderson et al. (9,10). The ventricular septum is separated into three separate components—an inlet septum, an apical trabecular septum, and an outlet or infundibular septum.

The inlet septum separates the mitral and the tricuspid valves. The trabecular portion extends from the chordal attachments of the tricuspid valve into the apex and superiorly to the crista supraventricularis. The outlet or infundibular segment is the smooth-walled portion which is in continuity with the crista supraventricularis and the pulmonary valve. The membranous septum is small and often is divided by the septal leaflet of the tricuspid valve.

The defects that extend into the membranous, inlet, or outlet septum have been termed perimembranous VSDs. This term also has been used to describe defects that lie in the outflow tract of the left ventricle (LV) just under the aortic valve. A descriptive synonym used for this particular location is an infracristal or membranous VSD. Inspection from the right

ventricle (RV) demonstrates that this defect is beneath the crista supraventricularis and posterior to the papillary muscle of the conus. Surgical and autopsy case series have shown that possibly 80% of the VSDs noted were within this region (11,12). It is common for these defects to extend into portions of the inlet, outlet, or muscular aspects of the septum and be classified as perimembranous. The perimembranous defect also may accompany abnormalities of the tricuspid valve, most often the septal leaflet. The abnormality of the tricuspid valve leaflet may be secondary to damage from the left-to-right shunt. One of those anomalies is the presence of septal leaflet tissue that can partially or completely obstruct the defect, otherwise known as an aneurysm of the ventricular septum. Another important characteristic of the perimembranous defect is the potential for malalignment. Anterior malalignment of the infundibular septum and the anterior ventricular septum have been associated with the aortic valve overriding the septal defect (9). A less commonly observed phenomenon is a posterior malalignment of the ventricular septum that could cause left ventricular outflow tract obstruction, specifically subaortic narrowing. Posterior malalignment commonly is associated with the VSD associated with aortic arch interruption. In the presence of a deficient tricuspid valve septal leaflet, a LV-right atrial (RA) shunt can occur. This more commonly occurs with the presence of both an LV-RV and LV-RA shunt. If there is no LV-RV shunt, delineation of tricuspid valve abnormalities should be sought, some of which include septal perforation, a deficient leaflet, or a tricuspid valve cleft. Rarely, the absence of atrioventricular septal tissue will result in an isolated LV-RA shunt (Gerbode defect).

Using surgical and autopsy case series, investigators have estimated that outlet-type VSDs constitute 5% to 7% of VSDs. These outlet type VSDs have been labeled suprastal, infundibular, conal, subpulmonary, or doubly committed subarterial defects. Population studies show that patients from Japan and other Far East nations have a much higher incidence of this type of VSD than Occidental populations. In Japan, outlet septal defects comprise 30% of all VSDs (9,11,13).

One type of inlet VSD, located posterior and inferior to the perimembranous region, has been mislabeled as an atrioventricular septal defect. The true atrioventricular septal defect is one in which there are abnormalities of the mitral and/or the tricuspid valve and the course of the conduction system is displaced. The inlet-type VSD has neither mitral nor tricuspid valve abnormalities and no evidence of displacement of the conduction system. From a surgical/autopsy case series review these VSDs comprised 3% to 8% of the total cases (11,12).

The incidence of muscular VSDs ranges from 5% to 20% in surgical and autopsy case series. These defects effectively can be described as either apical or central. The apical defects, as seen from the RV, can have multiple orifices and therefore present with multiple jets. Often, when evaluated from the left

ventricular aspect, these have a single point of origin from the LV. This type of defect can be quite large. The central-type defect, located in the midportion of the septum and posterior to the septal band of the crista, often can be hidden from the right ventricular view and can have multiple jets. As with the apical VSD, the left ventricular view can demonstrate a single well-circumscribed VSD that is away from the anterior and posterior walls of the LV. Another muscular type of VSD is the marginal or anterior septal wall defect. This type of defect commonly is described as a "Swiss-cheese" type septum comprised of multiple small, tortuous marginal defects. This type of VSD also can be associated with other muscular as well as perimembranous defects (10,14).

Patients with either outlet-type or perimembranous defects are at risk of developing aortic valve insufficiency. It is hypothesized that the outlet-type defect involves a deficiency of the muscular or fibrinous support underneath the aortic valve that may contribute to prolapse of an aortic valve cusp. The right coronary cusp most commonly prolapses into this type of defect. In contrast, the perimembranous defect more often is associated with prolapse of the right or noncoronary cusps. Generally, inlet-type and muscular-type defects are unassociated with prolapse of the aortic valve. According to a recent review, aortic insufficiency, caused by VSD flow disturbances is due to a lack of the necessary support for the aortic valve causing prolapse of the aortic valve cusp (15).

Identification of the nature of the defect also will allow an understanding of the course of the conduction system. In perimembranous defects, the bundle of His travels along the posterior and inferior rim of the defect as opposed to the inlet-type of defect in which it will be anterior and superior to the defect (10). Surgically induced atrioventricular block is less likely with an isolated muscular trabecular defect or an outlet-type defect because they are distant from the atrioventricular node and the bundle of His.

PHYSIOLOGY

The clinical manifestations of an interventricular ventricular left-to-right shunt largely are dependent on the size of the defect and the pulmonary and systemic vascular resistances. With small defects, the volume of the left-to-right shunt is limited by the resistance of the small defect. With larger defects, the volume of the left-to-right shunt depends upon the relative pulmonary and systemic vascular resistances.

Transition from fetal to extrauterine existence is associated with changes in the pulmonary vascular resistance. The small highly muscularized medial layer of the pulmonary arteries undergoes physiologic changes that result in a larger lumen and thinner-walled pulmonary artery. These changes result in declining right ventricular systolic pressure. By 7 to 10 days of life, the right ventricular pressure should have declined to normal. Infants born with large VSDs have a delayed decline in pulmonary vascular resistance that serves as a protective mechanism to prevent massive pulmonary overcirculation. Thus, it mainly is the pulmonary vascular resistance that determines the magnitude of the left-to-right shunt associated with large VSDs (16–18).

The size of the VSD can be compared to the aortic valve. This concept was proposed years ago by Dr. Nadas. Those defects that are less than one-third the diameter of the aortic valve are considered small and therefore restrict the amount of left-to-right shunting via the defect. For most of these restrictive defects, catheter-based data have demonstrated near-normal right ventricular pressure, pulmonary arterial pressure, and near-normal pulmonary vascular resistance

(19). The high resistance at the VSD results in a large difference of systolic pressure between the right and LVs. The peak gradient between the two occurs during systole. However, due to the large pressure difference, a continuous left-to-right shunt can be appreciated by color-flow Doppler interrogation.

Perimembranous and outlet defects often can have flow directed toward the right ventricular outflow tract and to the pulmonary artery. The moderate-sized defect (defined as >33% of the aortic valve annulus but <50% of the annulus) will offer some pressure restriction. Continuous-wave Doppler interrogation often will demonstrate a >20 mm Hg gradient through the defect. Most of these patients will have mildly elevated right ventricular pressure as well as mild elevation of the pulmonary arterial pressure. Typically, they have normal to near-normal pulmonary vascular resistance. Yet, there is a greater degree of volume overload, which explains, in part, the dilation of the left atrium and the LV.

A large VSD (>50% of the aortic valve annulus and a Doppler flow interrogation predicting <20 mm Hg gradient between the left and RVs) results in nearly systemic systolic pulmonary arterial pressures. As the infant ages, the pulmonary vascular resistance will continue to decline and the degree of pulmonary overcirculation will increase. The further rise in pulmonary pressures will be transmitted to the pulmonary veins and the left atrium causing pulmonary venous hypertension and left atrial hypertension and eventually an increase of LV muscle mass (20). As the pulmonary vascular resistance declines by 2 to 8 weeks of age, the pulmonary blood flow increases resulting in increased sympathetic tone and dilation of the left atrium and ventricle. The latter results in a shift in position along the Frank-Starling curve that can adversely affect ventricular mechanics. The ability of the infant to tolerate a large shunt is dependent upon the interplay between these competing factors.

As pulmonary vascular disease develops, the pulmonary vascular resistance increases and the left-to-right shunt reverses, and the presence of a right-to-left shunt will result in cyanosis (Eisenmenger complex or syndrome). Cyanosis will be accompanied by a right ventricular heave with a short or no systolic murmur. In this situation, other murmurs may be heard. A holosystolic murmur coincident with S1 from tricuspid valve insufficiency along with an early diastolic murmur of pulmonary valve insufficiency may be heard. The second heart sound will become loud, single or narrowly split. A third heart sound due to right ventricular filling may be appreciated (21,22). Wood described the clinical features of Eisenmenger syndrome including squatting and hemoptysis. Hemoptysis occurred in 33% of patients after 24 years of age and 100% of patients by 40 years of age. Early mortality was estimated to be 29%.

Pathologic analysis of patients with nonrestrictive pulmonary blood flow demonstrates that excessive pulmonary blood flow is deleterious to the small branch pulmonary arteries. Recent investigations have shown that chronic exposure to increased blood flow and pressure in the distal pulmonary arteries result in thickened adventitia, muscular medial hypertrophy, and potential intimal injury that can lead to thrombosis, ultimately causing pulmonary vascular obstructive disease (23,24). Patients with congenital heart disease and pulmonary vascular obstructive disease have plexiform lesions that express polyclonal endothelial cell proliferation as opposed to those with familial pulmonary artery hypertension that expresses monoclonal proliferating endothelial cells (25,26). Furthermore, genetic and molecular mechanisms currently are being elucidated to provide a better understanding of the changes that occur secondary to the abnormal flow and pressure patterns that occur in patients with large left-to-right shunts.

DIAGNOSTIC EVALUATION

Physical Examination

The physical findings for a patient with a VSD depend upon the size of the VSD, the magnitude of the left-to-right shunt, and the level of right ventricular and pulmonary artery hypertension and the balance of systemic and pulmonary resistances.

A small VSD with a $Qp/Qs < 1.5$ and normal or only slightly elevated right ventricular and pulmonary artery pressure is characterized by normal precordial impulses and normal first and second heart sounds. The murmur is S_1 coincident and holosystolic. In muscular VSDs, this murmur may be best heard over the lower sternal area. If the jet of blood through the VSD is directed toward the pulmonary artery, as is the case with many perimembranous and supracristal VSDs, the murmur radiates to the upper left sternal border. Frequently a precordial thrill is palpable.

For moderate and large VSDs, the right ventricular impulse, felt at the lower left sternal border or the subxiphoid region, is prominent. In addition, the left ventricular impulse will be displaced laterally and have increased activity. The first heart sound will be normal. As the degree of pulmonary hypertension increases, the intensity of the pulmonary component of S_2 will increase. There will be an S_1 -coincident holosystolic mid-frequency murmur. In patients with $Qp/Qs > 2$, in addition to the systolic murmur, there will be a middiastolic mitral flow murmur as a result of increased volume of blood flowing from the left atrium to the LV. A precordial thrill may be palpable and closure of the pulmonary and aortic valves may be palpable. Infants with a large VSD will be tachypneic. In addition, infants with severe congestive heart failure may have pallor, poor feeding, and failure to gain weight.

Electrocardiography

Small VSDs will have little effect on the QRS axis but large defects can be associated with left- or right-axis deviation. This may make it difficult to differentiate between a large VSD and an atrioventricular septal defect.

Moderate-sized defects are associated with chronic volume overload of the left atrium and ventricle resulting in left ventricular dilation and hypertrophy. Hypertrophy of both the right and the LVs is common (27). A moderate-sized VSD may or may not have electrocardiographic evidence of RVH.

Large VSDs in infants are difficult to diagnose solely using the ECG. Infants with moderate-sized VSDs often will demonstrate a counterclockwise frontal plane QRS axis. Patients with a large VSD have equalization of the ventricular pressures and, thus, have right ventricular hypertrophy. Patients with excessive pulmonary blood flow often will develop left atrial dilation, manifested by biphasic P waves in leads I, AVR, and V6. Prominent negative deflection of the P wave also can be seen in V1.

Patients with markedly elevated pulmonary vascular resistance in the setting of a large VSD rarely have evidence of left ventricular hypertrophy or left atrial dilation using ECG criteria. These patients will exhibit evidence of RVH.

Chest Radiography

Characteristic findings on chest radiographs vary depending upon the size of the VSD. Small defects with restrictive left-to-right shunting often will have a normal cardiac silhouette and normal pulmonary vascular markings. In contrast, patients with moderate to large VSDs will have cardiomegaly, increased pulmonary vascular markings centrally and peripherally,

possibly a dilated main pulmonary arterial segment, and/or elongation of the cardiac silhouette in a downward and leftward direction. Lateral projections may show upward deviation of the left main bronchus due to left atrial dilation. The standard posteroanterior projection also will demonstrate a change in the plane of the left main bronchus because of left atrial dilation.

Children with large VSDs and marked elevation of pulmonary vascular resistance can have normal cardiac size. Due to the frequent presence of right ventricular hypertrophy the cardiac apex is slightly rotated upward, leftward, and posteriorly. There often is marked dilation of the central branch pulmonary arteries as well as the main pulmonary artery segment. There will be increased peripheral vascular markings. For patients with Eisenmenger complex, the heart may not be enlarged and the pulmonary vascular markings may not be increased. The main pulmonary artery is enlarged.

Echocardiography

Transthoracic echocardiography is the mainstay for the definitive diagnosis of VSDs. It allows delineation of the location of the defect, associated cardiac lesions, pulmonary artery pressure, and degree of cardiac heart dilation.

In order to determine the anatomic site of the VSD, multiple echocardiographic imaging planes must be used. From the parasternal long-axis view data can be obtained regarding perimembranous, malalignment (Fig. 30.1), and muscular VSDs. Additional information is obtained via the parasternal long- and short-axis plane including the relationship of the perimembranous VSD to the septal tricuspid valve leaflet, secondary to flow disturbance that might distort the aortic valve's right coronary cusp (Fig. 30.2A,B), and the location and size of muscular defects (Fig. 30.3). The parasternal short-axis view also allows location of the position of the supracristal (subpulmonic) VSD (Fig. 30.4). The apical four-chamber view allows assessment of the isolated inlet VSD (Fig. 30.5), the muscular VSD, and the VSD associated with a complete atrioventricular septal defect. In addition, assessment of the left ventricular outflow tract allows evaluation of the perimembranous VSD. Aortic insufficiency can be quantified and billowing of the tricuspid valve septal leaflet through the VSD can be appreciated (Fig. 30.6). The subcostal short-axis plane is well suited for assessment of the common atrioventricular valve.

The subcostal as well as apical planes allow assessment of anterior deviation of the conal septum in the malalignment VSD associated with tetralogy of Fallot, the posterior mala-

Figure 30.7. Subcostal short-axis view at the level of the left ventricular outflow tract demonstrating posterior malalignment of the interventricular septum resulting in narrowing of the left ventricular outflow tract.

alignment VSD associated with interrupted aortic arch and subaortic membrane (Figs. 30.7 and 30.8A,B), and further delineation of the size and number of multiple muscular VSDs (Fig. 30.9).

Using the modified Bernoulli equation (pressure gradient in mm Hg = $4 \times \text{jet velocity}^2$) the gradient between LV and RV can be calculated. In some circumstances, right ventricular and pulmonary artery systolic pressure can be calculated. For example, with a systolic systemic blood pressure = 100 mm Hg, and a velocity across the VSD = 2 m/s, the right ventricular/pulmonary artery pressure can be calculated as $100 - 4(2)^2 = 84$ mm Hg.

The presence of left atrial or left ventricular dilation suggests that the VSD is hemodynamically important. Left-sided cardiac dilation correlates with a $Q_p:Q_s > 2:1$. The presence of significant chamber enlargement of or greater than one-half of systemic right ventricular pressure suggests the need for VSD closure.

Intraoperative transesophageal echocardiography (TEE) is utilized to clarify anatomic and physiologic details (Fig. 30.10). For example, the surgeon may want additional details about the anterior mitral valve cleft associated with complete atrioventricular septal defect. With aortic insufficiency, additional data can be obtained regarding the anatomy of the aortic valve, which might allow prediction of the likelihood of valve

Figure 30.9. Subcostal short-axis view at the level of the midinterventricular septum demonstrating color Doppler interrogation of a moderate-sized as well as a smaller low-muscular VSD.

repair. Postoperatively, one can ascertain the presence of residual ventricular-level shunting and pulmonary artery pressures.

TEE is useful to guide the implantation of an occlusion device during cardiac catheterization (Fig. 30.11). In addition, one can detect residual shunts, predict pulmonary artery pressure, and delineate problems such as distortion of the tricuspid valve as a result of device impingement upon the valve.

Magnetic Resonance Imaging

Didier et al. (28) demonstrated the use of MRI to determine the presence and location of VSD by voltage-gated imaging. Several investigators have quantitated pulmonary blood flow in the setting of left-to-right shunts (29). Most recently, investigators have correlated Q_p/Q_s by phase-contrast MRI and oxygen saturation measurement (30) (see Chapter 10).

Cardiac Catheterization

The primary indication for cardiac catheterization is to determine (a) the presence or absence of additional smaller defects and abnormalities, (b) quantitate the volume of shunting, (c) determine pulmonary vascular resistance, and (d) establish landmarks for possible transcatheter or surgical procedures.

Figure 30.8. A: Apical long-axis view of a large posteriorly malaligned VSD. Note the resultant narrowing of the left ventricular outflow tract. The LV is dilated due to pulmonary overcirculation. B: Apical long-axis view demonstrating color Doppler flow through an unobstructed, but narrowed left ventricular outflow tract due to posterior deviation of the interventricular septum in the setting of a malalignment VSD. Note the presence of mitral regurgitation.

Figure 30.10. Transesophageal echo long-axis view of a perimembranous VSD interrogation prior to surgical closure. The left image demonstrates the relationship of the VSD to the aortic and tricuspid valves. The right image demonstrates left-to-right color Doppler flow.

Right ventricular angiography allows one to determine the size and presence of muscle hypertrophy of the RV, evaluate pulmonary venous return, and assess intra-atrial shunting. Left ventriculography will demonstrate the presence or absence of left ventricular outflow tract anomalies, and the size, location, and number of VSDs (Fig. 30.12). To delineate the interventricular septum, the AP camera should be oriented to obtain a right-axial oblique view at about 30 degrees angulation and the lateral camera should be oriented to obtain a 60-degree long-axial oblique view with cranial angulation (31,32) (Fig. 30.13). If this view fails to adequately define the VSD, the “hepatoclavicular” or “four-chamber view” could allow for better delineation of those defects. This view is useful to delineate the course of the left ventricular outflow tract and demonstrate left ventricular–RA shunts (Gerbode defect).

Retrograde aortography can be used to determine the presence and degree of semilunar valve insufficiency, the coronary artery anatomy, the presence or absence of the ductus arteriosus, arch sidedness, and the presence or absence of a coarctation of the aorta.

If there is elevated pulmonary vascular resistance, one should perform a provocative test to evaluate pulmonary vascular reactivity. This is performed using 100% oxygen to produce pulmonary vasodilation. In addition, inhaled nitric oxide can be used if there is little or no decline with 100% oxygen. Additional drugs such as epoprostenol sodium (PGI_2) have

Figure 30.11. Transesophageal echo four-chamber view demonstrating successful Amplatzer VSD occlusion device deployment across a midmuscular VSD.

Figure 30.12. Retrograde pigtail catheter in the LV with the cameras in left anterior oblique with cranial angulation. This view demonstrates the interventricular septum and left-to-right shunt through a perimembranous VSD with aneurismal tissue obstructing some of the left-to-right flow. Mild mitral valve insufficiency is also noted.

been used to determine the degree of pulmonary vasoreactivity (33,34). Historically, patients who have irreversible elevation of PVR were considered to be poor candidates for surgical correction. Although the level of pulmonary vascular resistance that is considered incompatible with successful cardiothoracic

surgery has not been determined, a nonmodifiable pulmonary vascular resistance >6 to 8 Woods units \times m^2 has been considered predictive of reduced postoperative survival (35,36).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a large left-to-right shunt and pulmonary overcirculation includes atrioventricular septal defect with unrestricted pulmonary blood flow, double outlet RV, LV-RA shunts (Gerbode), patent ductus arteriosus, aorticopulmonary window, truncus arteriosus, congenitally corrected transposition of the great arteries with a VSD, and functional single ventricle without pulmonary stenosis among others.

Atrioventricular septal defects are differentiated from isolated VSDs using echocardiography and electrocardiography (see Chapter 29). Although atrioventricular septal defects typically have a northwest axis on the surface ECG, this can also be seen in an isolated VSD.

Patients with double outlet RV also may present with significant pulmonary overcirculation. One can differentiate an isolated malalignment VSD from double-outlet RV using echocardiography (see Chapter 51).

VSDs typically present with an S_1 -coincident holosystolic murmur that can sometimes be confused with the ejection murmur of pulmonary valve or subpulmonary or subaortic stenosis. Sometimes the ejection murmur of aortic stenosis in patients with high heart rates can be confused with that of a VSD. However, the murmur of aortic stenosis is ejection in timing, radiates into the neck, and usually is associated with an ejection click. The click is sometimes so prominent that the examiner thinks it is the first sound. It is important to listen “behind” the click to hear the softer S_1 . VSD can be associated with subaortic stenosis. Identification of associated anomalies is important when considering operation.

TREATMENT

Medical Therapy

Small VSDs do not cause significant pulmonary overcirculation. The outcome of these patients is excellent and medical therapy, surgical, or percutaneous closure of these defects are unnecessary.

Medical treatment of patients with large VSDs involves the use of diuretics, afterload reduction, and maximizing caloric intake. Diuretics are the first line of medical therapy. Furosemide (1 mg/kg to 3 mg/kg per day) divided into two or three doses relieves some of the increased preload and will reduce tachycardia and tachypnea. The use of furosemide may be complicated by hypokalemia, hypercalcemia, hearing loss, and possible renal toxicity. Spironolactone can be used as adjunctive therapy to prevent hypokalemia. A third line of medical therapy is afterload reduction. The concept behind afterload reduction is to shift the Qp/Qs more toward the systemic circulation and therefore reduce pulmonary blood flow (37). The efficacy of this approach has been documented in case-control trials from the late 1980s and early 1990s (38–40). Because angiotensin-converting enzyme inhibitors may cause potassium retention, spironolactone must be used carefully in conjunction with them.

The use of digoxin has gradually diminished over time. Hougren et al. (41) summarized the basic mechanisms of cardiac glycosides and their clinical use in heart failure in children. He noted that most pediatric patients with large left-to-right shunts have normal systolic ventricular function and

that these patients benefit little from the addition of digoxin. Others have made similar observations (42,43). However, digoxin continues to be used by some clinicians (44).

Over time, with medical therapy one may observe reduction in the volume of the left-to-right shunt due to spontaneous closure of the defect, increasing pulmonary vascular resistance, or hypertrophy of the right ventricular outflow tract portion of the right ventricle.

Patients with Eisenmenger complex will exhibit increasing cyanosis, decreasing exercise tolerance, and polycythemia (or erythrocythemia). Polycythemia can cause headaches and extreme fatigue. Relative iron deficiency is common in these patients and should be avoided or treated if it occurs. Symptomatic headaches and exhaustion can be ameliorated with partial exchange transfusion. Heart–lung transplantation may be a consideration for some of these patients. However, in the Second Natural History Study of Congenital Heart Disease, the 25-year survival for patients with Eisenmenger complex was 40%, which is superior to the 25-year survival after heart–lung transplantation. Often, these patients will need oxygen therapy and should be advised against living at high altitude due to the lower FiO_2 . If air travel is unavoidable, supplemental oxygen therapy should be provided since commercial aircraft often pressurize the cabin at 5,000 to 7,000 ft, lowering the FiO_2 accordingly.

SURGICAL THERAPY

Infants with a large shunt, congestive heart failure, and failure to thrive despite optimal medical therapy should have repair prior to 12 months of age both to eliminate congestive heart failure and to prevent the development of pulmonary vascular disease. For older children and adolescents with normal or reversible pulmonary vascular resistance but with a $Qp/Qs >2:1$, closure of the defect is indicated. Progressive aortic valve insufficiency associated with a supracristal (outlet) VSD is an indication for VSD closure. The surgical mortality in children is $<1\%$ to 3% (45).

Current practice guidelines suggest that adult patients with a Qp/Qs ratio >2 and echocardiographic evidence of volume overload of the left side of the heart or a history of infective endocarditis should have surgical closure (46,47).

Most perimembranous and inlet-type defects are closed using a transatrial approach. In contrast, defects that are associated with the outlet septum are best visualized and closed through the pulmonary valve. The approach more commonly used in the 1960s and 1970s employed staged palliation with the initial placement of a pulmonary artery band and subsequent debanding with VSD closure. The complications of pulmonary artery banding include inadequate or poorly controlled pulmonary blood flow, distortion of the main pulmonary arterial segment, and encroachment of the band on the proximal branch pulmonary arteries as well as possible interference of the band with pulmonary valve function including development of pulmonary valve stenosis. Because of these problems and because of improvements in infant surgery, pulmonary artery banding rarely is done in the modern era. Pulmonary artery banding may have a role in management of the premature or smaller infant (<3 kg) and patients with multiple VSDs (so-called Swiss cheese septum).

Another approach to patients with a “Swiss cheese” septum has incorporated the use of percutaneous or hybrid catheter (see Chapter 13) techniques to close one or more of the larger defects. Closure of large muscular defects from a left ventricular approach has been effective albeit with the potential for long-term adverse effect upon left ventricular function and the development of ventricular arrhythmias (48,49). Some investigators

Figure 30.14. Right anterior oblique orientation of anterior-posterior camera demonstrating the TEE probe and the prograde deployment of an Amplatzer muscular VSD device occluder.

have described the feasibility of percutaneous device closure of perimembranous and muscular VSDs (Fig. 30.14) (48,49) (see Chapter 13). Percutaneous techniques have been used to close postmyocardial infarction VSDs. The attractiveness of percutaneous closure lies in the avoidance of cardiopulmonary bypass and sternotomy, a shorter hospital stay, and decreased cost. The major drawback has been creation of atrioventricular conduction block. Follow-up studies of patients who have had percutaneous VSD closure have been limited to <10 years in contrast to the follow-up of surgical closure of the VSDs, which is now reaching 57 years. Early and delayed atrioventricular block occurs in fewer than 1% of patients after surgical closure of an isolated VSD, whereas atrioventricular block ranges from 3% to 20% after percutaneous closure (50,51,52).

In summary, use of percutaneous device occlusion has an increasing role in interventional pediatric and adult cardiology. However, investigators have demonstrated that surgical closure has excellent outcomes with low early and late postoperative complications as compared to patients who have had percutaneous occlusion. As techniques and materials improve, the outcomes of patients who have percutaneous occlusion undoubtedly will improve.

Postoperative sequelae

The presence of residual defects after surgical or percutaneous closure have been well documented (53,54). Postoperative evaluation should include a surface electrocardiogram, an echocardiogram to determine presence or absence of residual shunts, presence or absence of pericardial effusions, and a chest x-ray to evaluate heart size and presence or absence of pleural effusions. Common postoperative findings include right bundle branch block, especially if a right ventriculotomy was performed. Although rare, delayed complete heart block can occur after surgical VSD closure. Patients who have had a left ventriculotomy for either surgical or percutaneous access to muscular VSDs may exhibit abnormal left

ventricular wall motion, elevated left ventricular end-diastolic pressure, and or left ventricular systolic dysfunction. Small residual VSDs can occur. Most often, these are small defects either around the device or around the surgical patch; they may close spontaneously during the first year after closure. Repeat surgical intervention rarely is needed for small residual defects (<2 mm) (54).

CLINICAL OUTCOMES AND PROGNOSIS

The prognosis is good for most patients with small VSDs. They are at very low risk for the development of elevated pulmonary vascular resistance (27,55). Long-term studies have demonstrated that those patients have excellent outcomes and that mortality has been linked to the presence of associated semilunar valve problems (most commonly aortic valve insufficiency) or bacterial endocarditis (56). Kidd et al. concluded that the majority of patients fared well. Long-term survival at 25 years was approximately 87%. Despite this, there was a higher than normal 15-year prevalence of serious arrhythmia and sudden death among patients managed either medically or surgically (57). Similar findings were reported by Roos-Hesselink et al. in their review of 22- to 34-year postoperative outcomes of patients who had surgical repair of VSDs. A review of 176 consecutive patients between 1968 and 1980 at a single institution showed a survival rate of 92%. A 4% incidence of sinus node dysfunction requiring pacemaker implantation was noted. The incidence of pulmonary hypertension was 4% and the incidence of aortic valve insufficiency was 16%. The need for surgical reintervention was 6% (58).

Most (75% to 80%) small perimembranous-type defects and small muscular-type VSDs will close spontaneously within the first 2 years of life. However, untreated patients with large VSDs in infancy can die from congestive heart failure during the first 6 weeks to 6 months of life. With proper medical and surgical management, however, these patients should have an excellent outcome (59–65).

ACKNOWLEDGMENTS

We would like to thank the echocardiography staff at Seattle Children's Hospital for their tireless dedication to our patients and for their assistance in collecting the images presented in this chapter. Special thanks to Heidi Borchers, RDCS, Raylene Choy, RDCS, and Colleen Cailles, RDCS, RCS.

Patent Ductus Arteriosus and Aortopulmonary Window

Phillip Moore ■ Michael M. Brook

PATENT DUCTUS ARTERIOSUS

Anatomy

The ductus arteriosus, a large channel normally found in all mammalian fetuses, develops from the distal portion of the left sixth aortic arch and connects the main pulmonary trunk with the descending aorta, 5 to 10 mm distal to the origin of the left subclavian artery in a full-term infant. With a right aortic arch, the ductus arteriosus may be on the right, joining the right pulmonary artery and the right aortic arch just distal to the right subclavian artery; more commonly, it is on the left, joining the left pulmonary artery and the proximal portion of the left subclavian artery. Rarely, the ductus arteriosus may be bilateral. It varies in length and in the term fetus has a diameter of approximately 10 mm, similar to that of the descending aorta (1). The ductus is a tube with a relatively uniform diameter prior to closure; however when it remains patent postnatally it changes shape dramatically. Closure usually begins at the pulmonary artery end, so most often a patent duct is conical in shape, large at the aortic ampulla and narrowing toward the pulmonary artery entrance; however, there is great variability in the anatomical shape of the persistent ductus.

The microscopic structure of the ductus arteriosus differs from that of the adjacent pulmonary trunk or aorta. Although wall thicknesses are similar, the media of the latter are composed mainly of circumferentially arranged layers of elastic fibers, whereas the media of the ductus arteriosus consist largely of layers of smooth muscle arranged spirally in both leftward and rightward directions together with increased amounts of hyaluronic acid. The intimal layer of the ductus arteriosus is thicker than that of the adjoining arteries and contains an increased amount of mucoid substance. There are also small, thin-walled vessels in its subendothelial region (2,3).

Important associated structures to the ductus arteriosus include the recurrent laryngeal nerve, the phrenic nerve, and the thoracic duct. The recurrent laryngeal nerve arises from the vagus nerve anteriorly and caudally, coursing around the duct to ascend posteriorly to the larynx. It can be injured during surgical ligation as well as interventional treatment with devices and stents (4,5).

Physiology

Role in the Fetus

By 6 weeks of gestation, the ductus arteriosus is developed sufficiently to carry most of the right ventricular output. The relative sizes of the great arteries and the ductus arteriosus reflect the

proportions of cardiac output (combined ventricular output) carried by them (1). The right ventricle ejects about two-thirds of combined ventricular output, and because lung flow is only 6% to 8%, the ductus arteriosus carries 55% to 60% of combined ventricular output (6). The ductus arteriosus permits flow to be diverted away from the high-resistance pulmonary circulation to the descending aorta and the low-resistance placental circulation. A large pulmonary blood flow during fetal life would represent wasted circulation, and the ductus arteriosus therefore reduces the total workload of the fetal ventricles (6).

Whether the ductus arteriosus plays an active physiologic role during fetal life is unknown. It had been considered a relatively passive structure until it was shown that prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2) produce and maintain active relaxation (7–11).

Normal Postnatal Closure

Postnatal closure of the ductus arteriosus is effected in two phases. Immediately after birth, contraction and cellular migration of the medial smooth muscle in the wall of the ductus arteriosus produce shortening, increased wall thickness, and protrusion into the lumen of the thickened intima (intimal cushions or mounds), resulting in functional closure (3). This commonly occurs within 12 hours after birth in full-term human infants (12). The second stage usually is completed by 2 to 3 weeks in human infants, produced by infolding of the endothelium, disruption and fragmentation of the internal elastic lamina, proliferation of the subintimal layers, and hemorrhage and necrosis in the subintimal region. The mounds enlarge progressively, and there is connective tissue formation and replacement of muscle fibers with fibrosis and permanent sealing of the lumen to produce the ligamentum arteriosum (2).

The exact mechanisms responsible for the initial postnatal closure of the ductus arteriosus are not fully understood. During fetal life, the partial pressure of oxygen (pO_2) to which the ductus arteriosus is normally exposed is 18 to 28 mm Hg (6). An increase in pO_2 , as it occurs with ventilation after birth, constricts the ductus arteriosus in mature fetal animals (6,7,9,10,13); however, at about 0.6 gestation (term = 150 days), although capable of contracting, the ductus arteriosus is not constricted by increased oxygen even at high concentrations. With advancing gestation, the amount of constriction in response to increasing pO_2 is greater and the level of pO_2 required to initiate a response decreases (11,13). Other factors, such as the release of vasoactive substances (e.g., acetylcholine, bradykinin, or endogenous catecholamines), may contribute to postnatal closure of the ductus arteriosus under physiologic conditions (6,13).

Of greater importance is the role of prostaglandins, the cyclooxygenase-mediated products of arachidonic acid metabolism, in the ontogenic and overall physiology of the ductus arteriosus. Exogenous PGE₁, PGE₂, and PGI₂ dilate isolated ductus arteriosus strips or rings from term fetal lambs (7,8,10). Inhibitors of prostaglandin synthesis, either *in vitro* or when administered *in vivo* to pregnant animals near term, produce constriction of the ductus arteriosus (7,8,10), reversible by PGE₁ infusion (8), indicating that prostaglandins play an active role in maintaining the ductus arteriosus in a dilated state during normal fetal life. The exact sites of production of these prostaglandins *in vivo* are unclear. PGE₂ and PGI₂ are formed intramurally in the ductus arteriosus and may exert their action locally on muscle cells (7–9). Endogenous PGI₂ production is about tenfold that of PGE₂; however, PGE₂ is three orders of magnitude more potent than PGI₂ as a relaxer of the ductus arteriosus (7,9). Prostaglandins are detectable only in very low concentrations in adult plasma, and most are not thought to act as circulating hormones because of their rapid catabolism in the lung (9). The fetus, however, has high circulating concentrations of prostaglandins, particularly PGE₂, probably owing to low fetal pulmonary blood flow and therefore decreased prostaglandin catabolism in the lungs, as well as to the fact that the placenta produces prostaglandins (7–9).

The effects of prostaglandins, as well as of inhibitors of prostaglandin synthesis, vary at different gestational ages (7,9,11). Indomethacin constricts rings of ductus arteriosus from immature fetal lambs more than it does rings from close-to-term lambs. Both PGE₂ and PGI₂ relax the ductus arteriosus from immature lambs more than that from mature animals, reflecting the significantly greater sensitivity to PGE₂ and PGI₂ of the immature ductus arteriosus. This change in sensitivity is influenced by the increase in endogenous cortisol toward term. Thus, patency or closure of the ductus arteriosus represents a balance between the constricting effects of oxygen, and perhaps certain vasoconstrictive substances, and the relaxing effects of several prostaglandins (9,10). At birth, the placental source is removed, and the marked increase in pulmonary blood flow allows effective removal of circulating PGE₂ tipping the balance in favor of ductal closure.

Physiology of Patency

Ontogenic differences in physiologic factors almost certainly account for the higher incidence of persistent patency of the ductus arteriosus (PDA) in preterm infants (11). Sensitivity of ductus arteriosus smooth muscle to PGE₂ is highest in immature animals and decreases with advancing gestation. In term infants, responsiveness is lost shortly after birth; this does not occur in the immature ductus. Pulmonary metabolism is important in reducing circulating concentrations of PGE₂; because this function is significantly reduced in immature lungs, increased circulating concentrations of PGE₂ as well as increased sensitivity are important contributors to persistent patency in preterm infants.

Physiology of the Left-to-Right Shunt

As with all left-to-right shunts, with PDA three major, interrelated factors control the magnitude of shunting: the diameter and length of the ductus arteriosus, which governs the resistance offered to flow; the pressure difference between the aorta and the pulmonary artery; and the systemic and pulmonary vascular resistances.

Normally after birth, systemic vascular resistance (afterload) is high, whereas pulmonary vascular resistance decreases when ventilation begins. As a result, systemic arterial blood pressure becomes higher than that in the pulmonary artery. With a small PDA, a high resistance to flow is offered by the small cross-sectional opening of the ductus arteriosus, so that

the left-to-right shunt will be small despite the large pressure difference. However, with a large communication, pressures tend to become equal, and the magnitude of shunting is then determined by the relationship of the systemic and pulmonary vascular resistances. For this reason left-to-right shunting through a PDA has been defined as dependent shunting (14). Because systemic vascular resistance does not change significantly after birth, changes in pulmonary vascular resistance are the major determinants in regulating the left-to-right shunting through a PDA. This is particularly important in the first 2 months after birth, when pulmonary vascular resistance normally is decreasing.

The physiologic features associated with left-to-right shunting through a PDA depend on the magnitude of the left-to-right shunt and the ability of the infant to handle the extra volume load (15). The volume shunted left to right through the PDA increases left ventricular output (16) that normally is high in the immediate newborn period (17). The resultant increase of pulmonary venous return to the left atrium and left ventricle (LV) increases ventricular diastolic volume (preload) and thereby LV stroke volume (Frank-Starling mechanism). LV dilation will result in an increased LV end-diastolic pressure with secondary increase in left atrial (LA) pressure. This may lead to signs of overt left heart failure with LA dilation and pulmonary edema. Right ventricular failure may occur if there is a large PDA with pulmonary hypertension or pulmonary edema and an elevated LA pressure, in which case pulmonary vascular resistance may be increased. The net result of both these situations is an increased pressure load for the right ventricle. Left-to-right shunting through a stretched, incompetent foramen ovale secondary to LA dilation is a fairly common association (15).

Several compensatory physiologic mechanisms help to improve myocardial performance and thereby maintain a normal systemic output. In addition to the Frank-Starling mechanism, the sympathetic adrenal system is stimulated, as is the development of myocardial hypertrophy. Increased sympathetic stimulation leads to direct stimulation of nerve fibers within the myocardium, with local norepinephrine release as well as an increase in circulating catecholamines released from the adrenal glands. As a result, both the force of contraction and the heart rate are increased. These mechanisms are responsible for the rapid heart rate and the sweating often seen in infants with heart failure. If the increased volume load persists, hypertrophy of the ventricular myocardium will develop. Because of the diastolic runoff through the PDA, the overall resistance to the LV is low facilitating increased total LV output.

These compensatory mechanisms are ordinarily well developed in older children or adults; however, they are not as well developed in newborn infants and are even less so in prematurely born infants. It is most important, therefore, to consider the state of maturity (i.e., gestational age at time of birth) of an infant who has a PDA with left-to-right shunting. Many physiologic functions that are present in older children reach full maturation at different rates and periods of gestation. For example, sympathetic nervous innervation of the LV myocardium may be completed only at term, or even after term (18), so that in an infant born prematurely, sympathetic stimulation of the LV myocardium likely would be incomplete. Likewise, the myocardium in an immature animal responds less to stretch (Frank-Starling mechanism) than does that in a more mature animal (19). The structure of the immature myocardium, too, is quite different from that at term in that there are far fewer contractile elements (19). Premature infants often have lower than normal serum Ca²⁺ concentrations, and this too may affect myocardial performance (20). Probably for one or all of these reasons, premature infants with left-to-right shunts through a PDA develop LV failure earlier than their full-term counterparts and, in addition, with a smaller volume

load. Of considerable importance as well is maintenance of myocardial perfusion. Because coronary arterial blood flow to the LV occurs mainly during diastole and depends on the systemic arterial–intramyocardial diastolic pressure differences as well as the duration of diastole, alterations in either can affect coronary blood flow (21). A reduction in aortic diastolic pressure occurs in a large PDA, and with a significant shunt, LV end-diastolic pressure may be increased and cause an increase in subendocardial intramyocardial pressure. The development of tachycardia will reduce the diastolic period. All three factors may result in decreased myocardial perfusion in the presence of a large PDA.

Delivery of oxygen to the myocardium depends on not only the coronary blood flow, but also the oxygen content of arterial blood and the ability of arterial blood to deliver oxygen at the tissue sites. A low hemoglobin concentration caused by physiologic anemia in the newborn period, particularly in premature infants, or by repeated blood sampling as it occurs with intensive neonatal care, jeopardizes oxygen delivery to the myocardium as well as to other organs. A further important factor, particularly in premature infants, is the amount of fetal hemoglobin present. Because fetal hemoglobin has a low affinity for the organic phosphates such as 2,3-diphosphoglycerate, the facilitation of oxygen delivery to peripheral tissues is reduced. This effect is greater with higher amounts of fetal hemoglobin (22).

Effects on the Pulmonary Circulation and Lungs

A small communication has little or no effect on the pulmonary arterial circulation. However, with a large communication, systemic and pulmonary arterial pressures will equalize, and because of the high flow and pressure, the small pulmonary arteries may not undergo their normal postnatal maturational changes. The medial smooth muscle does not regress as rapidly as normal or to the same extent, so that pulmonary vascular resistance falls more slowly and less completely than usual.

Initially the increase in pulmonary vascular resistance is associated only with an increased amount of medial smooth muscle. However, true pulmonary vascular disease (23) may occur subsequently, manifested by intimal damage with cellular proliferation, hyalinization, and finally thrombosis and fibrosis of the small pulmonary arteries. As more small pulmonary arteries become involved in this process, the pulmonary vascular resistance increases, the left-to-right shunt diminishes, and eventually a right-to-left shunt occurs. In severe pulmonary vascular obstructive disease, arteriovenous malformations may form with resultant hemoptysis.

Pulmonary edema occurs commonly in premature infants with only a moderate shunt and without severe heart failure. Capillary permeability in newborn animals is greater than in adults, and may be even more pronounced in premature infants. A small elevation in pulmonary venous pressure therefore can produce significant pulmonary edema.

Physiology of Delayed Closure in Term Infants

Although functional closure of the ductus arteriosus typically is completed on the first day after birth, it may be delayed for several days. Because pulmonary vascular resistance decreases normally, flow will occur from the aorta into the pulmonary artery throughout this period of functional patency. On careful auscultation, therefore, a murmur may be heard in the first few hours of life in many infants (24). Two particular murmurs have been described: a crescendo systolic murmur and a continuous murmur with a crescendo systolic and diminuendo diastolic component. Neither murmur is very loud (grade 1 to 2 on a scale of 1 to 6), and

both may be accentuated, or possibly only heard, during inspiration; the murmurs are heard best in the second to third left intercostal space and do not radiate widely. Because pulmonary arterial pressure is normal, the pulmonic component of the second sound is of normal intensity and the second sound is often well split (24). As the ductus arteriosus constricts, the diastolic component becomes inaudible and leaves only a crescendo systolic murmur that usually disappears by the 2nd to 3rd day of life. The electrocardiogram (ECG) and chest roentgenogram in these infants are normal. Real-time two-dimensional echocardiography shows normal intracardiac structures, and the ductus arteriosus generally is visualized directly. Doppler and color Doppler evaluation invariably detect and delineate the flow patterns of the shunt across the ductus arteriosus into the main pulmonary artery (25–27). Retrograde aortic flow is not seen in these infants with a small ductus. Hemodynamic studies performed in these infants have shown small left-to-right shunts with normal arterial pressures.

During the initial hours of constriction, any condition that lowers arterial blood pO_2 or increases circulating blood PGE_2 concentrations may delay normal closure (28). Likewise, before true anatomic closure occurs, the functionally closed ductus arteriosus may dilate with a reduced arterial blood pO_2 (29) or increased PGE_2 concentration. This may occur in asphyxial states and in the presence of any one of many different pulmonary diseases (e.g., meconium aspiration). Residing at a high-altitude location, a nonpulmonary cause of arterial hypoxemia, has been shown to produce delayed closure of the ductus arteriosus. The incidence of PDA is about 30 times greater at high altitude (4,500 to 5,000 m) than at sea level (30). With severe pulmonary disease or persistent pulmonary hypertension syndrome of the newborn, when there is an increase in pulmonary vascular resistance, no shunt or even a right-to-left shunt through the PDA may occur. This leads to a lower pO_2 in the lower extremities than in the upper. This difference in pO_2 may persist for many days, and with pulmonary disease the ductus arteriosus may remain patent for several weeks.

The initial constriction of the ductus arteriosus is most prominent at its pulmonary arterial end and extends progressively toward the aorta, thus accounting for the predominant cone shape of the small PDA in which the diameter at the aortic end is considerably larger than at the pulmonary end. Even after the pulmonary arterial end has closed completely, the dilated aortic end of the ductus arteriosus may persist. This ductus ampulla, or ductus bump, may be evident on the chest roentgenogram (Fig. 31.1A,B) for several weeks (31).

Pathologic States

Premature Closure *in Utero*

In utero closure of the duct is well described. It can occur spontaneously, but is also associated with maternal use of nonsteroidal anti-inflammatory agents (NSAIDs) (32–34). Indomethacin appears to have the greatest effect, with the risk 15-fold higher than that of other NSAIDs (34). Interestingly aspirin does not appear to be associated with a significant risk for ductal closure (35), and no information exists about the risk of closure after ibuprofen exposure.

Premature closure of the duct *in utero* results in increased afterload on the right ventricle and increase pulmonary blood flow. This can lead to right ventricular failure, hydrops, and postnatal pulmonary hypertension (36). These can lead to increased risk for premature delivery, need for postnatal ventilation or extracorporeal support, and death. Fortunately, in the setting of NSAID usage, the effect on the duct is generally

Figure 31.1. A: Posterior-anterior chest roentgenogram of a 2-day-old infant demonstrating the ductus bump (arrow). B: Angiogram in the lateral position of a 5-day-old infant demonstrating the ampulla of the ductus arteriosus (arrow). Ao, aorta.

short lived and reversible when the medication is discontinued (37). The finding is easily seen using fetal echocardiography, which shows an increased diastolic velocity through the duct (38,39) (Fig. 31.2A,B).

Persistent Patency in Premature Infants

Delayed closure of the ductus arteriosus in preterm infants is well recognized (12,40–44). With the advent of techniques for maintenance of ventilation in premature infants, survival, particularly of small premature infants, has improved dramatically. Improvement of lung function with surfactant replacement therapy, by decreasing pulmonary vascular resistance, has led to the clinical emergence of PDA earlier and more frequently in preterm infants (45). Because the constrictor response of the ductus arteriosus to oxygen and the dilator effect of PGE_2 are closely related to gestational age (7,9,13), it is not surprising that there is an extremely high incidence of PDA in low-birth-weight preterm infants, particularly the very low-birth-weight infant (<1,000 g) and those with pulmonary disease. Approximately 45% of infants <1,750 g birth weight have clinical evidence of PDA, and infants <1,200 g birth weight have a prevalence closer to 80%. Overall, the incidence of PDA in preterm infants is about 8 per 1,000 of all live births.

The presence of a significant PDA in premature infants is associated with lower regional cerebral oxygen saturation (46) that implies reduced cerebral blood flow. In addition, studies have shown an elevated cardiac troponin T that normalizes after closure (47). These elevations are associated with increased morbidity and mortality (47) and worse 2-year neurodevelopmental outcome (48). These findings imply an inability of the immature myocardial and vascular systems to accommodate the increased volume load produced by the left-to-right shunt.

The clinical features depend on the magnitude of left-to-right shunt through the PDA and the ability of the infant to initiate compensatory mechanisms to handle the extra volume load. Because many premature infants have respiratory distress syndrome, the stage of development of this disease and the use of surfactant replacement therapy will determine the pulmonary vascular resistance and therefore the shunt. The maturity of the infant and the stage of myocardial development determine the ability to handle the shunt.

Three fairly distinct patterns of clinical presentation are recognized in these infants.

Patent Ductus Arteriosus with Little or No Lung Disease. In the first group, there is little or no underlying pulmonary disease (usually infants whose birth weight exceeds 1,500 g). However, smaller infants are encountered, and in many instances, their mothers have received steroid or other therapy prior to delivery,

Figure 31.2. A: Fetal echocardiogram with color-flow mapping showing constriction of the ductus. B: Spectral Doppler image of a fetal ductus showing continuous right-to-left flow with abnormally high diastolic velocities.

or the infants have received surfactant replacement therapy. A systolic murmur is first heard 24 to 72 hours after birth, and as the left-to-right shunt increases, this murmur becomes louder and more prolonged, extending to and often beyond the second heart sound into early diastole. The murmur commonly is heard best at the left sternal border in the second and third intercostal spaces. The classic continuous machinery murmur, described for older children with PDA, is not usual in premature infants, in whom the murmur generally has a high-frequency “rocky” quality. The pulmonic component of the second sound may become moderately accentuated. In the most mature infants in this group, a middiastolic flow rumble owing to increased diastolic flow across the normal mitral valve may be heard at the apex. If the shunt becomes large enough, a third heart sound due to rapid ventricular filling during diastole may be heard at the apex. The precordium becomes increasingly more hyperactive, the pulse pressure widens, and the peripheral pulses become more prominent and bounding as the left-to-right shunt increases. Increased peripheral pulses are best appreciated by the presence of palmar or forearm pulses.

If the shunt is allowed to become sufficiently large, clinical evidence of LV failure may appear. This includes tachycardia, tachypnea, and rales on auscultation of the lung fields. Associated with the development of pulmonary edema, there may be a decrease in arterial blood pO_2 . If LV failure were allowed to progress, a significant number of these infants might develop episodes of apnea, often associated with severe bradycardia. Enlargement of the liver will occur, but usually quite late.

The ECG is not helpful early in the disease, but if a moderately large shunt persists for several weeks, LV hypertrophy

and LA enlargement may become evident. The chest roentgenogram may show enlargement of both the left atrium and LV if there is a moderately large shunt, but heart size commonly is normal. Pulmonary vascularity is often increased. Dilation of the ascending aorta usually is not seen in premature infants, but may occur with a protracted moderately severe shunt.

A full echocardiographic and Doppler evaluation has become essential in the clinical management of PDA and in assessing the magnitude of the shunt (25,26,49,50). This also will exclude congenital heart lesions with similar clinical findings as well as LV failure owing to poor intrinsic myocardial function. LA diameter varies with the size of the infant, so the ratio of the LA diameter to the aortic root (Ao) diameter, as measured from the parasternal long-axis echocardiographic view of the heart, can be used to determine LA enlargement. The normal LA:Ao ratio in infants is between 0.8 and 1. A ratio >1.2 suggests LA enlargement, which, in the absence of LV failure due to some other cause (such as aortic or mitral valve abnormalities or volume overload), most often indicates a significant left-to-right shunt. In the premature infant this is likely to be through a PDA. Two-dimensional echocardiography is now used to accurately assess LA and ventricular size directly. The dynamics of both LV and descending aortic wall motion also indicate the magnitude of shunt. Direct visualization of the ductus arteriosus (Fig. 31.3A) confirms the diagnosis. Doppler techniques (pulsed, continuous wave, and color) are applied to the evaluation of flow patterns in infants with PDA and are most helpful (26) (Fig. 31.3B). Flow from the aorta into the pulmonary artery can be detected, and velocity profiles of flow in the main pulmonary artery, ductus arteriosus, and descending aorta

Figure 31.3. A: Echocardiogram in parasternal short axis demonstrating a patent ductus arteriosus with color-flow mapping indicating reversed flow. B: Continuous wave Doppler echocardiogram positioned through the PDA, showing retrograde flow throughout the cardiac cycle. C: Pulsed-Doppler echocardiogram shows increased diastolic flow in the branch pulmonary artery. D: Parasternal long axis showing LA and left ventricular enlargement.

in infants with PDA have been characterized. Doppler color-flow mapping (27) also allows visualization of the extent of flow disturbance in the main pulmonary artery and the direction of the flow jet. Estimates of pulmonary arterial pressure also can be made if systemic arterial blood pressure is known (51).

Cardiac catheterization and angiography in these infants now is unnecessary because of the complete diagnostic information obtained by echocardiography. If performed, catheterization reveals moderate elevation of pulmonary arterial pressures and left-to-right shunting through the ductus arteriosus (40).

The use of biomarkers in the presence of PDA has been evaluated. As early as 1987, it was known that natriuretic peptide levels were abnormally elevated in the presence of a PDA (52). More recently, B-type natriuretic peptide (BNP) has been studied in the presence of a PDA in premature infants. BNP has been shown in adults to correlate with LV volume overload and LV failure (53). Small studies have shown that BNP levels are elevated in the presence of a large ductal shunt in premature infants (54,55). BNP levels decrease in both term and preterm infants rapidly after birth (56,57). In patients with a significant ductal shunt and elevated BNP levels, closure of the PDA results in a fall in BNP levels (58,59). BNP therefore, may be helpful in the screening and evaluation of newborn premature infants with a suspected ductal shunt, but its role in older infants (>2 weeks) or in asymptomatic patients has yet to be investigated.

Many infants in this group do not develop severe LV failure and ordinarily are easily managed with specific medical therapy to constrict the ductus arteriosus or conventional medical therapy of mild heart failure in preterm infants, fluid intake restriction, diuretics, and maintenance of hematocrit above 45%. Very rarely, intractable heart failure develops, necessitating urgent surgical closure. More often existing premature lung disease, active or resolving, adds to respiratory and feeding difficulties, which prompt treatment. If left alone, the ductus arteriosus closes spontaneously in most of these infants, commonly within 2 to 3 months after birth.

Patent Ductus Arteriosus in Infants Recovering from Lung Disease. The second and most common group of infants develops left-to-right shunting while recovering from severe or moderately severe respiratory distress syndrome. These infants usually weigh 1,000 to 1,500 g at birth. The idiopathic respiratory distress syndrome usually is evident within a few hours after birth, and if it follows the usual course, starts to improve after 3 to 4 days. As this improvement continues, early clinical evidence of a left-to-right shunt through a PDA appears. In addition, at about this age, fluid administration generally is increased to deliver adequate calories; this often aggravates the volume-loading effects of the left-to-right shunt on LV function. Probably the ductus arteriosus has been patent since birth and the pulmonary disease with a resultant increase in pulmonary vascular resistance has prevented a detectable left-to-right shunt. As the pulmonary disease improves, oxygenation increases and the ductus arteriosus should constrict. However, most of these infants are quite immature, so a good constrictor response may not occur. Many of these infants are still maintained on mechanical ventilators or continuous positive airway pressure (CPAP), so that careful clinical assessment is required to establish the presence of a shunt through the ductus arteriosus. In many instances the murmurs are not audible until the infant is briefly detached from the ventilator or CPAP system. Because recovery from the respiratory distress syndrome often is not continuously progressive but is interspersed with periods of deteriorating lung function, left-to-right shunting (and therefore the murmur) may be intermittent for several days. The murmur commonly disappears and reappears several times within short periods of time. Initially a systolic murmur alone is heard; however, as the shunt

increases, the murmur extends into diastole. The murmur is similar in distribution and quality to that in the first group of premature infants with PDA. Because infants in the second group are usually more immature than those in the first, LV failure may occur in them when clinically there seems to be less left-to-right shunting. A third sound often is heard, but a mid-diastolic flow rumble is uncommon. The pulmonic component of the second sound ordinarily is already accentuated because of the pulmonary disease but may become louder as the shunt increases. Increasing precordial activity is a good clinical indication of the magnitude of shunting in these infants, and increased heart rate, pulse pressure, and bounding pulses with a rapid upstroke are often detectable early. Palmar or forearm pulses are often palpable. Because most of these infants have indwelling umbilical arterial catheters, careful monitoring of the umbilical arterial blood pressure often shows a widening pulse pressure and a decrease in diastolic pressure as left-to-right shunting develops.

Rales are unreliable as an index of pulmonary edema and LV failure because they may be suppressed by positive pressure ventilation used in these infants. However, in those extubated who have recovered sufficiently from their respiratory distress syndrome, rales may be heard. Apneic episodes are also common in this group and may be associated with short periods of bradycardia.

Deterioration in the ventilatory status of an infant recovering from respiratory distress syndrome is often a strong indication of a significant left-to-right shunt through a PDA. However, other causes, such as recurring lung disease and pneumothorax or sepsis, should be actively excluded. Deterioration of the ventilatory status is manifested by the requirement for an increasing concentration of inspired oxygen, alterations in ventilator rate or pressure settings, increased requirements of CPAP, and assisted ventilation and increasing arterial blood $p\text{CO}_2$. The ECG often shows increased right ventricular forces owing to the underlying pulmonary disease but generally is of little help. A chest roentgenogram will show the parenchymal changes of respiratory distress syndrome, and increased pulmonary vascularity therefore may be extremely difficult to assess. Cardiomegaly is variable, particularly if the infant is being artificially ventilated; however, increasing cardiomegaly may indicate an increasing shunt.

Because many of the changes described may be due to deterioration resulting from underlying pulmonary disease, it is important to be able to assess the contribution to the clinical picture of a PDA. For this purpose, the echocardiogram usually is very helpful. An increasing LA:Ao ratio will be produced by increasing left-to-right shunting, whereas a ratio that remains constant and within normal limits may indicate non-cardiac causes of deterioration. Changes in the LV, left atrium, and PDA size assessed reliably by two-dimensional Doppler echocardiography will determine the role of shunting through the PDA. It should be emphasized that very early diagnosis is possible with two-dimensional Doppler echocardiography, which is completely noninvasive and safe. In addition, BNP can be quite useful in these patients to indicate significant overcirculation. This, coupled with current, more aggressive management approaches, has altered the natural history of PDA so that infants rarely are allowed to develop many of the signs described above.

Patent Ductus Arteriosus Associated with Lung Disease. The third group consists of infants who have severe respiratory distress syndrome from birth. Because many of these are very low-birth-weight infants (<1,000 g), the likelihood of a PDA being present is very high (>80%). A few show no clinical signs even when carefully evaluated—the “silent” ductus arteriosus (60). Many do show clinical evidence of a left-to-right shunt through the PDA, or fail to show improved respiratory status at an age when they should start to recover from the primary

pulmonary disease. They too are extremely sensitive to small increases in Na^+ and fluid administration. They require ventilatory assistance by mechanical respirators or CPAP. Deterioration commonly is manifested by the need for increasing ventilator pressure, rate, or oxygen, or CPAP support. Failure to improve is manifested by the inability to wean the infant from ventilatory support. An increase in arterial blood $p\text{CO}_2$ is common. Murmurs may be difficult to hear, and in some of these infants, the ductus arteriosus may be so widely patent that a murmur is not produced (61). Changes in the ventilatory status may be due to progression of the primary pulmonary disease, and it is often even more difficult to separate LV failure from increasing pulmonary problems than in the previous group. Increasing precordial activity, bounding pulses, and a widening arterial pulse pressure suggest the development of left-to-right shunting. When present, the murmur is usually only systolic, the pulmonic component of the second sound is accentuated, and a gallop rhythm is often heard. The ECG and chest radiograph usually are not helpful, but as outlined above, the two-dimensional Doppler echocardiographic evaluation is diagnostic even before clinical signs are apparent.

Persistent Patency in Term Infants, Children, and Adults

The incidence of isolated PDA in full-term infants is about 1 in 2,000 live births (62), accounting for about 5% to 10% of all types of congenital heart disease. Unlike the ductus arteriosus in premature infants, in whom failure of closure is due to physiologic developmental retardation, the ductus arteriosus in full-term infants is abnormal, and failure to constrict is probably related to a significant structural abnormality.

PDA may occur in more than one member of a family, suggesting possible genetic factors in certain instances. PDAs have been produced by genetic inbreeding in poodles (63). Gene linkage and chromosome analysis studies in humans have shown abnormalities on chromosome 12 in isolated PDA patients in Iran (64) and on chromosome 16 in association with aortic aneurysm (65).

In mature infants, older children, and adults, the factors determining the clinical features are the same as in premature infants, namely, the size of the communication, the relationship

between pulmonary and systemic vascular resistances, and the ability of the myocardium to handle the extra volume load.

Small Ductus Arteriosus. With a small communication, pulmonary vascular resistance and therefore pulmonary arterial pressure normally decrease after birth. However, because the resistance to flow across the ductus arteriosus is high, only a small left-to-right shunt develops. Pulmonary blood flow is increased only minimally, and LV failure does not occur. Therefore, few patients are symptomatic, and attention is often brought to this condition only by the murmur detected at a routine physical examination.

Physical growth is normal except in those children who are otherwise predisposed to poor growth, such as those in whom maternal rubella was present. The peripheral pulses may be full, and the arterial pulse pressure is slightly increased unless the shunt is very small. Precordial activity usually is normal with no increased apical impulse. First and second heart sounds are normal, and the only significant abnormal auscultatory finding may be the presence of a murmur. In early infancy, before pulmonary vascular resistance has decreased completely, there may be a short period in which no murmur is heard. A short systolic murmur may then be heard, which may progress to the typical, continuous murmur heard in older children. This murmur is heard best in the second left intercostal space and often is accentuated when the patient is recumbent or during inspiration. Administration of a vasoconstrictor agent such as phenylephrine raises systemic vascular resistance and increases left-to-right shunt, and the murmur will become longer and louder. The important features of the characteristic continuous murmur first described by Gibson (66) are the late systolic accentuation and continuation through the second sound into diastole. The murmur ordinarily starts shortly after the first sound, peaks at the second heart sound, and fades away, ending in the last third of diastole.

The ECG and chest roentgenogram are usually normal in these children; however, slight prominence of the main and peripheral pulmonary arteries may be seen on the roentgenogram (Fig. 31.4A). The two-dimensional echocardiogram Doppler study will delineate the PDA size and flow patterns as described before.

Figure 31.4. Posterior–anterior chest roentgenograms in two children each with a patent ductus arteriosus. A: A 4-year-old child with a small left-to-right shunt. Slight cardiomegaly and prominence of the pulmonary vasculature are present. B: A 4-year-old child with a very large left-to-right shunt. A double density and elevation of the left mainstem bronchus are present owing to LA enlargement. The LV, main and peripheral pulmonary arteries, and ascending aorta are prominent. Pulmonary venous congestion is also present.

Moderate Ductus Arteriosus. In infants, a moderate left-to-right shunt may produce symptomatology related to LV failure. Poor feeding, irritability, and tachypnea may be present, and weight gain is often slow. The symptoms ordinarily increase until about the 2nd to 3rd month of age. If the LV failure does not produce severe disease at this stage, compensatory myocardial hypertrophy occurs, and in many instances these infants improve considerably. Some, in fact, are detected only on subsequent routine physical examination, but close questioning will yield the previous abnormal history. General physical development can be slightly retarded, and easy fatigability may be present in the older child. The pulse rate is often increased, with the peripheral pulses full and bounding. The systemic arterial pressure is widened with a low diastolic pressure. The precordium is hyperdynamic, and LV enlargement produces a thrusting apical impulse. A systolic thrill may be palpable at the upper left sternal border. Both the first and second sounds may be difficult to hear, because they often are masked by a loud murmur. A third heart sound is often heard at the apex. The progression from a systolic murmur to a continuous murmur is considerably more rapid in these infants than in those with a small shunt. The continuous murmur is more intense, has more extensive radiation, and generally is well heard posteriorly. It has a much harsher quality with low-frequency components, and because of the large flow and great turbulence, eddy sounds that vary from beat to beat give the murmur a machinery quality.

If heart failure occurs, the murmur may lose its continuous character and occupy only systole. A middiastolic, low-frequency, rumbling murmur is ordinarily heard at the apex. Early pulmonic or aortic ejection sounds may occur. The increased LV stroke may produce a functional systolic pressure difference across the aortic valve that may be manifested by a soft ejection systolic murmur. In early infancy, LV failure with increased LA size and pressure often induces a left-to-right shunt through a stretched and incompetent foramen ovale (15). Depending on the magnitude of left-to-right atrial shunting, right ventricular hyperactivity may become evident and the right ventricular outflow murmur typical of atrial left-to-right shunting may be heard. In addition, a middiastolic flow rumble owing to the increased flow across the tricuspid valve may be audible at the lower left sternal border.

The ECG may be relatively normal during infancy, but LV hypertrophy is usual in older infants and children. The mean frontal plane axis usually is normal. LV hypertrophy is manifested by a deep Q wave and a tall R wave in leads II, III, aVF, and the left precordial leads V5 and V6. The T waves in these leads ordinarily are upright and show increased amplitude. A pattern compatible with left bundle branch block also has been described in some children. A widened P wave indicating LA enlargement may be present. If there is a left-to-right atrial shunt as well as mild pulmonary hypertension, right ventricular hypertrophy may increase the amplitude of the R waves in the right precordial leads. Right atrial enlargement may increase the height of the P wave.

The chest roentgenogram shows an enlarged heart with prominence of the LV and the typical signs of LA enlargement (Fig. 31.4B). The main pulmonary artery segment is prominent, and the pulmonary vascular markings in the peripheral lung fields are increased. The ascending aorta is often very prominent. The two-dimensional echocardiogram demonstrates increased LA and ventricular diameters, hypertrophy if present, and the PDA itself. Doppler evaluation will demonstrate flow and velocity patterns and will allow for an estimate of pulmonary arterial pressure (51).

Large Ductus Arteriosus. Infants with a large PDA are invariably symptomatic. They are irritable, feed poorly, fail to gain weight normally, tire easily—particularly while feeding—and sweat excessively. They have increased respiratory effort

and respiratory rates, also aggravated by feeding, and are prone to develop recurrent upper respiratory infections and pneumonia. These symptoms indicative of severe LV failure with pulmonary edema may occur early in infancy.

Many of the typical physical signs may be absent when there is severe LV failure. However, tachycardia and tachypnea are present, and if there is pulmonary edema, rales will be heard throughout the lung fields. The respiratory signs may be suggestive of pneumonia. The peripheral pulses are bounding with a rapid upstroke and a wide pulse pressure unless there is severe LV failure when the pulse volume decreases. The precordium is markedly hyperdynamic, and clinical evidence of cardiac enlargement is present. The LV apical impulse is thrusting and, if right ventricular enlargement occurs, may be accompanied by a left parasternal impulse. A systolic thrill is often palpable. The first and second heart sounds are accentuated, and a third sound ordinarily is heard at the apex. Occasionally no murmur is heard, especially with severe failure. When LV failure is controlled, a moderately loud systolic murmur is heard best in the pulmonary area or occasionally in the third or fourth intercostal space. The murmur peaks late in systole, and the prolongation into diastole is variable; the murmur commonly ends within the first third of diastole. The typical continuous murmur heard with a small or moderate-sized PDA may be heard but is less usual. A prominent middiastolic mitral flow rumble commonly is audible at the apex.

The ECG shows more prominent LV hypertrophy, with deep Q and taller R waves than in the previous group. The T waves may be diphasic or even inverted. Right ventricular hypertrophy may be evident, with upright T waves in the right precordial leads and increased R-wave amplitude in the right precordial leads. LA enlargement, as demonstrated by a widened P wave, also will be seen. The chest roentgenogram shows striking enlargement of the heart with predominant LA and LV enlargement. The main pulmonary artery segment usually is markedly enlarged, and the peripheral pulmonary vascular markings are markedly accentuated. Evidence of LV failure with increased pulmonary venous markings and interstitial fluid also may be seen. With an enlarged left atrium or pulmonary arteries, lobar collapse or emphysema owing to bronchial compression may occur. The two-dimensional echocardiogram/Doppler study is as described for the previous group.

Infants with large left-to-right shunts through a PDA may not survive the resultant heart failure without treatment. However a certain proportion of those capable of compensating adequately survive the initial period. A moderate or large left-to-right shunt either undetected in infancy or treated but allowed to persist eventually leads to the development of obstructive pulmonary vascular disease. As pulmonary vascular resistance increases, pulmonary hypertension increases until systemic levels are reached. The left-to-right shunting decreases and this leads to improvement in the infant's symptomatology and signs, usually 8 to 15 months after birth. Feeding problems, poor weight gain, and the increased sweating previously present disappear, with far fewer episodes of respiratory infection. The murmur becomes shorter, and the diastolic component may be completely lost. The middiastolic rumble decreases and disappears, and the first heart sound becomes softer. The second heart sound remains markedly accentuated, but the third heart sound disappears. Precordial hyperactivity diminishes, and the pulses become less bounding. The chest roentgenogram shows decreasing pulmonary vascularity, and a decrease in heart size also may be noted. The period of time over which these changes occur varies and may last several years, but irreversible changes are common after 15 to 18 months of age.

As the increased pulmonary vascular resistance progresses to irreversible pulmonary vascular disease, the symptoms and

Figure 31.5. A: Angiogram in the lateral position in a newborn infant with pulmonary atresia. The typical anatomy associated with right ventricular outflow obstruction is demonstrated. The aorta is widely dilated, and the aortic isthmus is wider than the descending aorta. The typical tortuous ductus arteriosus with an acute rather than the normal obtuse inferior angle with the aorta is present. This orientation is consistent with aorto-to-pulmonary arterial blood flow in fetal life. Ao, aorta; DA, ductus arteriosus; MPA, main pulmonary artery. B: Lateral distal transverse angiogram in an infant with pulmonary atresia after placement of a ductal stent to maintain patency.

clinical features change even further. The murmur continues to shorten until eventually it disappears. The second sound becomes single and progressively louder, an ejection systolic click occurs, and a faint blowing early-diastolic regurgitant murmur owing to pulmonary incompetence may be heard at the upper left sternal edge. LV hyperactivity disappears, and the right ventricular parasternal impulse increases. The ECG shows increasing right ventricular hypertrophy with dominant R waves in the right precordial leads. Peaked P waves indicative of right atrial enlargement also may occur. The chest roentgenogram shows increasing right ventricular enlargement with decreasing LV size, a large main pulmonary artery, and progressive decrease in peripheral vascular markings.

Cyanosis, often more pronounced in the lower than in the upper limbs, begins to appear, initially only with exertion, but eventually becoming continuous as persistent right-to-left shunting across the ductus arteriosus occurs. The final picture, if allowed to progress, is one of irreversible pulmonary vascular disease with marked right-to-left shunting. The precordial activity is now dominantly right ventricular, and the pulses are either of normal or small volume. The second heart sound typically is palpable in the pulmonic area, and a diastolic thrill also may be felt. The first heart sound is slightly accentuated, and the pulmonic component of the second heart sound is markedly accentuated. A harsher and longer early diastolic blowing murmur caused by pulmonary incompetence is heard at the left sternal border. A blowing systolic murmur owing to secondary tricuspid insufficiency may be heard at the lower left sternal border. The ECG shows right-axis deviation in the frontal plane with marked right ventricular hypertrophy and eventually T wave inversion in older patients. The chest roentgenogram shows moderate cardiomegaly with predominant enlargement of the right ventricle and a markedly enlarged main pulmonary artery with prominence of the central vessels but no peripheral plethora. Right atrial enlargement may be evident.

Role of the Ductus Arteriosus in Complex Congenital Cardiac Malformations

In right ventricular outflow obstruction lesions such as pulmonary atresia, the normal flow patterns in fetal life are altered, and development of the ductus arteriosus is probably abnormal (1,67). The diameter is large and orientation is vertical from the underside of the aortic arch (Fig. 31.5A). Because patency of a PDA is essential for maintenance of pulmonary blood flow, the constrictor response to an increase in pO_2 is undesirable. Despite the hypoxemia in these infants, the ductus arteriosus closes, resulting in cessation of pulmonary blood flow, progressive hypoxia, acidosis, and death. PGE_1 is currently used as pharmacologic prevention of this closure before the creation of a surgical aortopulmonary communication. PGE_1 produces dilation of the ductus arteriosus with a significant increase in systemic arterial pO_2 (68). Systemic oxygenation is markedly improved, acidemia reversed, and the infants ordinarily can be stabilized for days to weeks before palliative surgery. Maintenance of patency for a more prolonged period has been produced by placement of a metal intravascular stent in the PDA (69–73) (Fig. 31.5B). Early results are encouraging with excellent pulmonary artery growth (74) but technical issues may favor use in less tortuous ducts found most commonly in lesions such as pulmonary atresia with intact ventricular septum.

Maintenance of systemic blood flow in hypoplastic left heart lesions such as aortic or mitral atresia or in interrupted aortic arch depends on PDA. PGE_1 has proved extremely valuable in improving lower body perfusion in these infants. Acidemia is often reversed and renal function markedly improved so that the infants can be stabilized and returned to electrolyte and hemodynamic balance before corrective surgery is undertaken (68). More recent developments in the initial palliative treatment of hypoplastic left heart syndrome have included the placement of a metal stent in the ductus arteriosus and banding of the pulmonary arteries (hybrid approach) to stabilize systemic and pulmonary

blood flow until infants reach the age of 4 to 6 months at which time surgical Glenn shunt with arch reconstruction is performed. It has yet to be shown whether this new approach will have significant advantages, but early results show a potential for decreased early mortality in high-risk patients with comparable late mortality in experienced centers (75–77). There is a significant incidence of transverse aortic arch obstruction after PDA stenting (>25%) that may require additional intervention (78).

It has been shown that the ductus arteriosus plays an important role in the presentation of infants with juxtaductal aortic coarctation. Localized coarctation ordinarily is produced by a well-circumscribed posterior shelf protruding into the aortic lumen at a point opposite the insertion of the ductus arteriosus (1). If the ductus arteriosus remains patent or if there is a well-formed ductus ampulla even when the ductus arteriosus is closed, obstruction by the juxtaductal coarctation may not occur. However, as the ductus arteriosus closes and the ampulla retracts, progressive interference with flow occurs, and clinical symptoms and signs will develop. The sudden occurrence of acute LV failure in infants with juxtaductal coarctation of the aorta may be produced by rapid constriction of the ductus arteriosus in the postnatal period. PGE₁ has been of great benefit in the management of these infants as well (75). In the rare child or adult with a persistent PDA in the setting of coarctation, covered stent repair has been shown to be an effective nonsurgical treatment alternative (Fig. 31.6A,B).

Clinical Differential Diagnosis

Venous Hum

The continuous bruit produced by flow through the large veins in the neck is often confused with the continuous murmur of a PDA. The venous hum varies in intensity with head and neck position as well as the phase of respiration and is usually obliterated by firm pressure over the neck, by turning the head to one side, or by lying flat.

Total Anomalous Pulmonary Venous Connection

Unobstructed total anomalous pulmonary venous connection to the innominate vein occasionally produces a continuous

murmur very much like a venous hum. The other features of this lesion serve to differentiate it from a PDA.

Ruptured Sinus of Valsalva

Rupture of one of the sinuses of Valsalva into either the right atrium or right ventricle is accompanied by a continuous murmur. However, onset of symptoms and signs in this condition is usually abrupt and often follows trauma to the chest. The murmur is usually heard lower in the precordium.

Arteriovenous Communications

Arteriovenous fistulas involving one of the coronary arteries, an intercostal artery, or an internal mammary artery may be associated with continuous murmurs similar to those occurring in PDA. The murmurs typically are more superficial and sound extracardiac in origin. Origin of one of the pulmonary arteries from the aorta (hemitruncus arteriosus) also may produce a continuous murmur, as may lobar sequestration, in which an anomalous artery arising from the aorta supplies one or more pulmonary lobes. Pulmonary arteriovenous fistulas may produce a continuous murmur, but when large enough to do so are usually associated with cyanosis and classical radiographic findings.

Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery

In this lesion, retrograde flow occurs from the right coronary artery into the pulmonary artery. If this retrograde flow is sufficiently large, a continuous murmur may be heard, but this is rare. The clinical presentation and ECG are diagnostic of this condition.

Absent Pulmonary Valve
